The main body of woodcocks generally arrive in two flights, known to east-coast sportsmen as the 'first flight,' and after this the 'great flight.' In the autumn of 1884 the immigration of this species was most prolonged, commencing on September 1, and continuing onward to January 20, 1885, or 142 days. Four distinct rushes or flights are indicated: October 5 and 6, another on the 10th to the 16th, a third, probably the 'great flight,' on the 28th; and again a very large flight between November 11 and 13—a flight which also extended very far north, to the Pentland Skerries. The dates of the chief flights across Heligoland will be found to correlate very closely with the arrivals on the east coast. Very few woodcocks are recorded from the west coast of England. The notes, however, taken from October 8 to 14, at the Nash East Lighthouse in the Bristol Channel, on this species are very interesting. The mean time of arrival may be fixed at 3.30 A.M. On the 8th a bird, after flying round the light, went off in a south-westerly direction. It is fair to presume that these woodcocks formed part of the great flight which we know

[1] Mr. J. A. Harvie-Brown.

crossed Heligoland from the 12th to the 15th, and are also shown to have arrived on the east coast between October 10 and 16. Woodcocks migrate by night, and probably start on their journey in the dusk of evening. Supposing them to have left the coast of Denmark at 5 P.M., and travelling from north-east to south-west across Heligoland, so as to arrive at the Nash light at or about 3.30 A.M., the distance traversed would be 550 miles in $10\frac{1}{2}$ hours, or about 52 miles an hour, a rate of progress, from what we know of the flight of birds, probably nearly the correct one. A large majority of the various birds which strike the lanterns of west coast lighthouses do so between midnight and daybreak, which is suggestive of a continuous and uninterrupted flight across the North Sea and the breadth of England.

An unusually extensive migration of gulls to the Scotch coasts was remarked in 1884, in connection with the vast swarms of sprats or 'garvies' (*Clupea sprattus*), themselves following and feeding on countless myriads of minute marine creatures. This aggregation has been attributed, and perhaps with reason (though it is a point on which the Committee has not sufficient information to decide), to the vast accumulation of ice west of Spitzbergen in the summer of 1884, and the consequent lowering of the temperature of the sea, which cause has impelled and driven southward the fish food along the course of the milder Gulf Stream to the uttermost limits of its possible extension, the firths and inlets of the east coast of Scotland.

As a rule very few of our rarer immigrants are recorded from the east coast of Scotland. The king-eider was seen off the Isle of May on September 24, and the black redstart is recorded from the same station and Pentland Skerries. On the east coast of England, besides the bluethroats, already noticed, several rare and casual visitants have been recorded during the autumn: two examples of the barred warbler, one at Spurn Point and another on the Norfolk coast; the icterine warbler, also on the Norfolk coast; and an ortolan, likewise from the same locality. The Lapland bunting, in Lincolnshire and Norfolk; Tengmalm's owl, in Holderness; and a rose-coloured starling, near Spurn.

On the west coast of England the report embraces notes on some rare and interesting species, including the white wagtail, Pallas's grey shrike, waxwing, Cassin's snow-goose, garganey teal, red-necked phalarope, ruff, black tern; whilst the scarcity or entire absence of the tree sparrow, hooded crow, and brent goose, and the presence of the bernacle goose, are of interest to one accustomed to east-coast observations. The capture, too, of eight storm-petrels at the South Bishop, on October 14, is a noteworthy incident. The lanterns vary not a little in their death-dealing attractions, those of the Bardsey, South Bishop, Smalls, Nash (E), Godrevy, and Eddystone lighthouses being most seductive, occasionally commanding no less than two hundred victims in a single night.

From the Irish coasts it is reported that in 1884 the number of birds was equal to, and in a few instances above, the average.

The great bulk of migrants arrive on the southern half of the east coast of Ireland, and on the easternmost of the southern counties—in other words, along the shore extending from Dublin to Waterford, and having its limits at Rockabill Lighthouse and Dungarvan Lighthouse.

A *marked* migratory movement might be expected in the north-eastern counties between Scotland and Ireland, where the Irish Channel is narrowest; but we do not find such to be the case.

The usual course taken by birds seems to be either N.W. or S.E. The number of birds which only occur singly and do not seem to migrate in flocks is large. In such instances it is difficult to trace the line of migration.

The occurrences now noted of the Greenland falcon properly belong to the same flight that has already been noticed in last year's report.

As might be expected, the snow bunting is of more frequent occurrence on the western and northern coasts. A few remained as late as the first week in May, and it was again seen early in September, dates which have not hitherto been recorded in Ireland. Geese were also more numerous on the north and west coasts.

A remarkable migration of the rook was observed at the Tearaght and Skelligs, both stations being several miles off the coast of Kerry. It lasted for three weeks, from November 2 to 20, the direction of flight being from west to east. The light-keepers were puzzled to know whence the birds could have come, the nearest land to the west being America, in which this species is not found.

Mr. Gätke's Heligoland notes, from June 28 to the end of the year, comprise 118 species, including, as usual, several rare visitors to the ornithological observatory:—Icterine Warblers on Aug. 18; *Anthus richardi*, Sept. 3 to Oct. 12: *A. campestris*, Sept. 4; *Carpodacus erythrinus*, Sept. 9; *Anthus cervinus*, a great many, from Sept. 15 to Oct. 12; *Lanius major*, in most unusual numbers, from. Sept. 17 to Nov. 4; *Alauda cristata*, Sept. 30 and Oct. 1; *Saxicola stapazina* (?), Oct. 2; *Turdus varius*, Oct. 3, 12, and 23, one each day: *Emberiza pusilla*, Oct. 5, two; *Turdus migratorius*, one on Oct. 14; *Fringilla rufescens*, our English redpoll, one on Nov. 22. Besides these large numbers of continental species, which are classed amongst the rare and occasional visitants to the British Islands, and whose line of migration is normally far to eastward of these islands, as *Emberiza hortulana*, *Motacilla flava*, *M. alba*, *Cyanecula suecica*, *Anthus rupestris*, *Plectrophanes lapponicus*, *Otocorys alpestris*, *Nyctala tengmalmi*, *Ruticilla titys*, *Regulus ignicapillus*, and *Larus minutus*.

The great rush of birds crossed Heligoland during the last fortnight in October, and appears to have come directly across to our eastern shores. Mr. Gätke remarks, under date Oct. 24, S.E., clear, fine, early rather cold, *C. cornix*, *C. frugilegus*, and *C. monedula*, 'monstrous numbers;' *cornix* and *monedula* mixed in uninterrupted flights of ten and twelve minutes each, continued with but short interruptions or gaps; width as far as the eye could reach in northerly and southerly directions; and thus from 9 A.M. till 1 P.M. *Sturnus*, 'a succession of clouds sweeping past overhead.'

The Committee have again to thank Professor Chr. Fr. Lütken, of Copenhagen, for a list of the birds killed against the lighthouse of Stevns, on the projecting part of Zealand, marking the limit between the Baltic and Oresund.

In conclusion your Committee would take the opportunity of thanking the Master and Elder Brethren of the Trinity House, the Commissioners of Northern Lights, and the Commissioners of Irish Lights for their ready co-operation and assistance, through their intelligent officers and men, in the inquiry.

The Committee respectfully request their reappointment.

Report of the Committee, consisting of General Sir J. H. LEFROY, Lieut.-Colonel GODWIN-AUSTEN, Mr. W. T. BLANFORD, Mr. SCLATER, Mr. CARRUTHERS, Mr. THISELTON-DYER, Professor STRUTHERS, Mr. G. W. BLOXAM, Mr. H. W. BATES (*Secretary*), Lord ALFRED CHURCHILL, Mr. F. GALTON, and Professor MOSELEY, *appointed for the purpose of furthering the Exploration of New Guinea, by making a grant to Mr. Forbes for the purposes of his expedition.*

THE Committee beg leave to report that the grant of 200*l*. voted by the Association towards the expenses of Mr. H. O. Forbes' expedition was paid to Mr. Forbes on January 9 last, and that he sailed from England early in April. In a letter from Batavia, dated June 30, Mr. Forbes says that he arrived at that port on May 8, and that his time in the interval had been occupied in a journey to Amboyna and back, made for the purpose of securing the services of four hunters, whose abilities and fidelity had been tested on his former journeys in various islands of the Archipelago. The four hunters had been engaged, as also twenty native carriers, a number which it would be necessary to increase to twenty-five. He had arranged to leave Batavia in the steamer for Thursday Island, Torres Straits, about July 13, and hoped to reach that station on the 20th of the same month. At Thursday Island he would be joined by his assistant, Mr. Thiele, and would then decide whether he would make the southern coast of New Guinea, near Port Moresby, his starting point into the interior, or Dyke-Acland Bay on the north-eastern coast.

Report of the Committee, consisting of General Sir J. H. LEFROY, the Rev. Canon CARVER, Mr. F. GALTON, Mr. P. L. SCLATER, Professor MOSELEY, Dr. E. B. TYLOR, Professor BOYD DAWKINS, Mr. G. W. BLOXAM, and Mr. H. W. BATES (*Secretary*), *appointed for the purpose of furthering the scientific examination of the country in the vicinity of Mount Roraima in Guiana, by making a grant to Mr. Everard F. im Thurn for the purposes of his expedition.*

THE Committee beg leave to report that the sum of 100*l*. granted by the Association has been paid to Mr. Everard im Thurn, whose report, together with the map of the neighbourhood of the mountain from the surveys of Mr. H. J. Perkins, a member of Mr. im Thurn's expedition, was published in the number for August, 1885, of the 'Proceedings of the Royal Geographical Society,' who had contributed 200*l*. towards the cost of the expedition.

Report of the Committee, consisting of the Rev. Canon TRISTRAM, the Rev. F. LAWRENCE, *and* Mr. JAMES GLAISHER (*Secretary*), *appointed for the purpose of promoting the Survey of Palestine.*

THE Survey of Eastern Palestine has been carried on during the last year privately by Herr G. Schumacher, C.E., assisted by Mr. Laurence Oliphant, who has also furnished the Committee with valuable notes of personal exploration in the district now called Junlau—the ancient Gaulanitis. The portion surveyed by Herr Schumacher consists of about 200 square miles, and covers an area previously quite unknown. The map, which is now in the hands of the Committee, is accompanied by voluminous memoirs and a great number of sketches, drawings, and plans of ruins figured for the first time. These drawings are now in the hands of the engravers, and it is proposed to publish them, with the memoirs, in October. The map will be laid down on the sheet to which it belongs. It is hoped that Herr Schumacher may be able to continue working in this way for the Society, so that, though it may be found impossible to send, as before, a large and well equipped party of Royal Engineers to survey the country, we may yet be continuously working, always extending our map, and acquiring new knowledge of this little-visited district. As regards other portions of the Holy Land, the map of the Wady Arabah has been laid down in the Society's sheets; the geological memoirs compiled by Professor Hull after his expedition of 1883–1884 are nearly ready, and will be issued before the end of the year; and the Society has been enabled to secure Mr. Chichester Hart's Natural History memoir, made from new observations during the same journey. In addition to Mr. Laurence Oliphant's paper, the Committee have received from Mr. Guy le Strange, and published, observations and notes made by him during a recent journey east of Jordan. The results of the survey, so far as it has been completed, will appear in a map reduced to a scale of about three miles to an inch, showing the country on both sides of the river Jordan, instead of on the western side only. The Old and New Testament names, with tribe boundaries and later divisions, have also been prepared for this map, and will be printed upon it in colour. A list of ancient names with modern identifications has been prepared, and will be issued with it. This portion of the work is under the direction of Colonel Sir Charles Wilson, K.C.M.G., F.R.S. The Society has also issued during the last year a popular account, by Professor Hull, of his recent journey, called 'Mount Seir,' and reprints of Captain Conder's popular books 'Tent Work in Palestine,' and 'Heth and Moab.' Finally, the Committee have completed the issue of their great work, the 'Survey of Western Palestine,' with the last volumes of 'Jerusalem,' the 'Flora and Fauna,' and a portfolio of plates showing the excavations and their results.

Report of the Committee, consisting of Dr. J. H. GLADSTONE (*Secretary*), Mr. WILLIAM SHAEN, Mr. STEPHEN BOURNE, Miss LYDIA BECKER, Sir JOHN LUBBOCK, *Bart.*, Dr. H. W. CROSSKEY, Sir RICHARD TEMPLE, Sir HENRY E. ROSCOE, Mr. JAMES HEYWOOD, *and* Professor N. STORY MASKELYNE, *appointed for the purpose of continuing the inquiries relating to the teaching of Science in Elementary Schools.*

THE principal duty of your Committee is to watch the course of legislative action as far as it has any bearing on the teaching of science in elementary schools; and naturally the annual modifications of the Educational Code claim the first consideration. This year, however, these modifications have been exceedingly small, and there is but one which affects the teaching of science, and that only indirectly.

Drawing has been made a class subject in the schools, and is to take its place with English, geography, elementary science, history, and needlework (for girls). Grants may be earned for three of these subjects. If one only is taken, it still must be 'English.' If three of these are taken, one of them must be 'drawing'; but if two are taken, the choice of the second subject lies between any of those that come after 'English.' Hence the addition of drawing reduces the chance of either of the scientific class subjects (geography or elementary science) being taught in elementary schools.

The Revised Instructions to Her Majesty's Inspectors issued this year contain the following additional clauses on geography, which meet with your Committee's entire approval:—'Geographical teaching is sometimes too much restricted to the pointing out of places on a map, and to the enumeration of such details as the names of rivers, towns, capes, and political divisions. It is hardly necessary to say that geography, if taught to good purpose, includes also a description of the physical aspects of the countries, and seeks to establish some associations between the names of places and those historical, social, or industrial facts which alone make the names of places worth remembering. It is especially desirable in your examination of the Fourth and higher Standards, that attention should be called to the English colonies and their productions, government, and resources, and to those climatic and other conditions which render our distant possessions suitable fields for emigration, and for honourable enterprise.'

As to the effect of the regulations on the teaching of these class subjects, the annual return of the Education Department shows that the teaching of geography is actually diminishing in our schools, and that elementary science has scarcely gained a footing. The following table shows the position of affairs, the figures for 1882–3 being calculated on the basis that the departments examined in the last four months of that year were 31·1 per cent. of the whole:—

Class Subjects		1882–3	1883–4
Geography	Departments	12,823	12,775
Elementary Science	,,	48	51
History	,,	367	382
Needlework	,,	5,286	5,929
		18,524	19,137

In regard to the scientific specific subjects, the following are the numbers of children individually examined, the figures for the year 1882–3 being computed as before :—

Specific Subjects		1882–3	1883–4
Algebra . . .	Children	26,547	24,787
Euclid and Mensuration	,, ...	1,942	2,010
Mechanics, A. . . .	,, ...	2,042	3,174
,, B. . . .	,, ...	——	206
Animal Physiology .	,, ...	22,759	22,857
Botany	,, ...	3,280	2,604
Principles of Agriculture	,, ...	1,357	1,859
Chemistry	,, ...	1,183	1,047
Sound, Light, and Heat	,, ...	630	1,253
Magnetism and Electricity	,, ...	3,643	3,244
Domestic Economy .	,, ...	19,582	21,458
Extra (Physiography) .	,, ...	——	16
		82,965	84,515

It will be seen that a slight increase has taken place in the aggregate number, but this is not at all in proportion to the increase in the number of children presented in Standards V., VI., and VII.—viz. 286,355 in 1882–3, and 325,205 in 1883–4. Next year's return will indicate more clearly what changes are taking place in the popularity of the different subjects; but it would appear that botany is decreasing, while mechanics, sound, light, and heat, and the principles of agriculture are making a decided advance.

This increase in the study of mechanics is no doubt partly due to the peripatetic method of teaching this subject which has proved so successful in Liverpool and Birmingham. It has just been commenced in one district in London.

The Report of the Committee of Council on Education, which has just been issued, makes the following comments on the small extent to which science is taught in our elementary schools :—

'The wider range of class subjects allowed by the Code under the head of "Elementary Science" does not appear to be taken advantage of to any great extent at present.'

'As to specific subjects . . . only 20·49 per cent. of the scholars eligible for examination in a specific subject have been so examined.'

It also draws attention to the proportionate amount of the Government grant paid for instruction in the various subjects in the boys' and girls' schools (excluding infants). It would appear that, out of a total of 17*s.* $2\frac{1}{2}$*d.* per head, less than $1\frac{1}{4}$*d.* is for specific subjects, while $8\frac{1}{4}$*d.* is given for singing alone.

It should, however, be mentioned that a few more children are studying some branch of science in classes under the Science and Art Department in some of our best schools.

In regard to technical education, it will be remembered that at the Southport meeting a recommendation was passed that this Committee 'be requested to consider the desirableness of making representations to the Lords of the Committee of Her Majesty's Privy Council on Education in favour of aid being extended towards the fitting up of workshops

in connection with elementary day schools or evening classes, and of making grants on the results of practical instruction in such workshops under suitable direction, and, if necessary, to communicate with the Council.'

The Committee awaited the appearance of the second report of the Royal Commissioners on Technical Instruction, and at the meeting at Montreal merely expressed a thorough approval of the recommendations of the said Commissioners:—'That proficiency in the use of tools for working in wood and iron be paid for as a specific subject, arrangements being made for the work being done, so far as practicable, out of school hours. That special grants be made to schools in aid of collections of natural objects, casts, drawings, &c., suitable for school museums.'

Last February, however, your Committee reported to the Council that they did consider it desirable to make representations to the Education Department, and suggested that the encouragement for the teaching of handicraft might take the form of that recommended by the Royal Commissioners on Technical Instruction; or that 'the use of tools' in boys' schools might be placed in the same position as 'practical cookery' in girls' schools. The Council received the report, but did not see their way to proceed further in the matter.

In the meantime, a very interesting experiment is being made by the Birmingham Board at the Bridge Street Seventh Standard School. This is an attempt to add to the education given in the public elementary schools a practical training in the use of ordinary workshop tools and sound elementary instruction in those sciences and arts upon which the trades and manufactures of Birmingham are based, such as theoretical and practical mechanics, chemistry, electricity, model and machine drawing, and the principles of machinery. Although it is necessary to prepare for examinations by Her Majesty's Inspector under the Code, all the subjects are taught on lines which will have a practical and technical bearing. A two years' course of instruction has been arranged, the subjects taken being:—Arithmetic, algebra, Euclid, theoretical chemistry, practical chemistry, drawing (solid geometry, free-hand). In the second year electricity is added.

The London Board has just arranged an experiment for teaching the use of tools to a class of boys on Saturday mornings in the Carlton Road school. It is confined to working in wood, and follows the plans adopted in the Slöyd system, which is carried out to such a large extent in Sweden, and has been introduced into some other parts of the Continent. It is proposed also to try another experiment at Beethoven Street School, Kensal, with Seventh Standard boys. It will take more the form of practical carpentry.

Report of the Committee, consisting of Sir FREDERICK BRAMWELL (*Secretary*), Professor A. W. WILLIAMSON, Professor Sir WILLIAM THOMSON, Mr. ST. JOHN VINCENT DAY, Sir F. ABEL, Captain DOUGLAS GALTON, Mr. E. H. CARBUTT, Mr. MACRORY, Mr. H. TRUEMAN WOOD, Mr. W. H. BARLOW, Mr. A. T. ATCHISON, Sir R. E. WEBSTER, Mr. A. CARPMAEL, Sir JOHN LUBBOCK, Mr. THEODORE ASTON, *and* Mr. JAMES BRUNLEES, *appointed for the purpose of watching and reporting to the Council on Patent Legislation.*

ON August 14, 1885, an Act was passed entitled 'An Act to amend the Patents Designs and Trades Marks Act' of 1883.

This amending Act consists of six sections, the first and second of which relate to matters of form.

The third section deals with an extension of time which under certain circumstances might be allowed for the reception of the complete specification and for the sealing of the patent.

The fourth section is a very important one. It provides for that which the members of this Committee and the Committee of the Society of Arts desired to see introduced into the Act of 1883, viz., that where an application for a patent has not been perfected, the specification, with its drawings, if any, left in connection with the application, shall not at any time be open to public inspection or be published by the Comptroller.

In the view of the Committee this is a most salutary provision. As the law stood, the publication of crude and immature ideas, meaningless at the time, but to which a meaning might be given when success had been attained by some independent inventor, frequently prevented such inventor from obtaining a valid patent, to the great loss of the public as well as of himself.

In at length introducing this provision into the Patent Act, the Government has followed the plan pursued in the United States in respect of the document which, so far as its citizens are concerned, is the equivalent of our provisional specification.

The Committee regard this fourth section with great satisfaction, as showing that it is at last recognised to be for the benefit of the public not to throw open new inventions, but to give an inventor the strong personal interest which induces him to push his invention into practical work. In fact, the truth of the oft-quoted saying of the late Sir William Siemens, that 'if an invention were found lying in the gutter, it would be in the interest of the public to assign it to some person as owner,' is admitted.

Section 5 is also important as clearing up a doubt whether, under the Act of 1883, a patent could be lawfully granted to two or more persons, when some of the persons to whom it was granted had not had any part in the invention. Section 5 of this Act of 1885 declares that it has been, and is, lawful, under the Act of 1883, to grant a patent under such circumstances.

The sixth and last section relates to a slight, but not unimportant, alteration in section 103 of the Act of 1883. This section (section 103) has not yet attracted as much public attention as its importance demands. Many of the Governments of Europe, including Great Britain, have entered into a Convention by which they are endeavouring to introduce an International Patent Law. It has been officially announced that England

has complied with all necessary formalities, so that it is to be assumed that this law is already in force. Its effect will not be inconsiderable: as the date of applying for a patent in any country of the Union fixes the time from which the applicant may be entitled to a patent in all the other countries, even though he may not apply in the other countries for a considerable time after having made application in his own, and even though others may have applied in the meantime. Section 103 of the 1883 Act provided in effect that if Her Majesty became a party to the Convention, an applicant from any of the States of the Union should be entitled to an English patent in priority to other applicants, and that his patent should have the same date as the date of the protection obtained in such foreign State. The amendment made by the sixth section of the Amending Act is to change the words 'date of the *protection*' which occur in section 103 of the Principal Act, into 'date of the *application*,' which seems to be more in accordance with the terms of the Convention.

The Committee desire to be reappointed, in order to be in a position to watch the working of the Principal Act, of this Supplementary Act, and of the International Convention, and to report upon any amendments that may be proposed in any of them.

The Committee would be glad for the grant of 5*l.* for expenses to be renewed.

Report of the Committee, consisting of Dr. E. B. Tylor, Dr. G. M. Dawson, General Sir J. H. Lefroy, Dr. Daniel Wilson, Mr. Horatio Hale, Mr. R. G. Haliburton, *and* Mr. George W. Bloxam (*Secretary*), *appointed for the purpose of investigating and publishing reports on the physical characters, languages, industrial and social condition of the North-western Tribes of the Dominion of Canada.*

The Committee have been in active correspondence with missionaries and others stationed among the Indians, but the unsettled state of the country during the past year has made it impossible to do more than collect materials for a preliminary report; the Committee, therefore, ask that they may be reappointed, with a continuance of the grant.

Report on the Blackfoot Tribes. Drawn up by Mr. Horatio Hale.

The tribes composing the Blackfoot Confederacy, as it is commonly styled—in some respects the most important and interesting Indian communities of the North-west—have been until recently less known than any others. It seemed, therefore, that the best contribution which a single member could make to the general report of the Committee would be a special study of these tribes. This view was confirmed by the opinion of President Wilson, the only other member of the Committee who was near enough for me to consult with. With his aid a correspondence was opened with two able and zealous missionaries residing among these Indians, both of whom have replied most courteously and liberally to my inquiries. These are the Rev. Albert Lacombe, widely and favourably known as Father Lacombe, Roman Catholic Missionary among the Siksika, or proper Blackfeet Indians, and the Rev. John McLean, Missionary of the Canadian Methodist Church to the Blood and

Piegan (or Kena and Piekanè) tribes. Father Lacombe has been many years a missionary in the Canadian North-west, and has a very extensive knowledge of the tribes of that region. His elaborate work, the 'Grammar and Dictionary of the Cree Language,' ranks among the best contributions to American philology. Mr. McLean has been engaged in his missionary duties for five years, has prepared a grammar of the Blackfoot language, and is at present occupied in translating the Scriptures into that tongue; he has been most considerate in furnishing the information which was requested on behalf of the Committee, and is now making special researches for this object.

The unfortunate troubles of the past season have for a time interrupted the correspondence, and have left the investigations necessarily incomplete. The principal portion of the report on these Indians will therefore have to be deferred for another year. It has seemed advisable, however, to submit a summary of the knowledge now obtained by way of introduction to the fuller account which the Committee may be able to render hereafter. With this view some other sources of information have been examined, particularly the valuable official reports and maps of the Canadian and United States Indian Departments, which have been obligingly furnished by those Departments for this purpose.

Fifty years ago the Blackfoot Confederacy held among the western tribes much the same position of superiority which was held two centuries ago by the Iroquois Confederacy (then known as the 'Five Nations') among the Indians east of the Mississippi. The tribes of the former confederacy were also, when first known, five in number. The nucleus, or main body, was—as it still is—composed of three tribes, speaking the proper Blackfoot language. These are the Siksika, or Blackfeet proper, the Kena, or Blood Indians, and the Piekanè, or Piegans (pronounced Peegans), a name sometimes corrupted to 'Pagan' Indians. To these are to be added two other tribes, who joined the original confederacy, or, perhaps more properly speaking, came under its protection. These were the Sarcees from the north, and the Atsinas from the south. The Sarcees are an offshoot of the great Athabascan stock, which is spread over the north of British America, in contact with the Eskimo, and extends in scattered bands—the Umpquas, Apaches, and others—through Oregon and California into Northern Mexico. The Atsinas, who have been variously known from the reports of Indian traders as Fall Indians, Rapid Indians, and Gros Ventres, speak a dialect similar to that of the Arapohoes, who now reside in the 'Indian Territory' of the United States. It is a peculiarly harsh and difficult language, and is said to be spoken only by those two tribes. None of the Atsinas are now found on Canadian territory, and no recent information has been obtained concerning them, except from the map which accompanies the United States Indian Report for 1884, and on which their name appears on the American Blackfoot Reservation.

The five tribes were reckoned fifty years ago to comprise not less than thirty thousand souls. Their numbers, union, and warlike spirit made them the terror of all the western Indians on both sides of the Rocky Mountains. It was not uncommon for thirty or forty war parties to be out at once against the Salish (or Flatheads) of Oregon, the Upsarokas (or Crows) of the Missouri plains, the Shoshonees of the far south, and the Crees of the north and east. The country which the Blackfoot tribes claimed properly as their own comprised the valleys and plains

along the eastern slope of the Rocky Mountains, between the Missouri and the Saskatchewan. This region was the favourite resort of the buffalo, whose vast herds afforded the Indians their principal means of subsistence. In the year 1836 a terrible visitation of the small-pox swept off two-thirds of the people, and five years later they were supposed to count not more than fifteen hundred tents, or about ten thousand souls. Their enemies were then recovering their spirits, and retaliating upon the weakened tribes the ravages which they had formerly committed.

In 1855 the United States Government humanely interfered to bring about a complete cessation of hostilities between the Blackfoot tribes and the other Indians. The Commissioners appointed for the purpose summoned the hostile tribes together, and framed a treaty for them, accompanying the act by a large distribution of presents. This judicious proceeding proved effectual. Dr. F. V. Hayden in his account of the Indian Tribes of the Missouri Valley (published in the 'Transactions of the American Philosophical Society for 1862'), states that from the period of this treaty the Blackfoot tribes had become more and more peaceful in their habits, and were considered, when he wrote, the best disposed Indians in the North-west. He remarks that their earlier reputation for ferocity was doubtless derived from their enemies, who always gave them ample cause for attacking them. He adds: 'From my own experience among them, and from information derived from intelligent men who have spent the greater portion of their lives with them, I am convinced that they are among the most peaceable and honourable Indians in the West; and in an intellectual and moral point of view they take the highest rank among the wild tribes of the plains.'

This favourable opinion of Dr. Hayden, it may be added, is entirely in accordance with the testimony of the Indian agents and other officials of the Canadian North-west, who place the Blackfeet decidedly above the surrounding tribes in point of intelligence and honesty. At the present time, while constantly harassed on their reserves by the incursions of thievish Crees and other Indians, who rob them of their horses, they forbear to retaliate, and honourably abide by the terms of their treaty, which binds them to leave the redress of such grievances to the Dominion authorities. It has seemed proper to dwell upon this point, as the marked differences of character among the Indian tribes has been too little regarded. As a question of science and a matter of public policy, these differences deserve a careful study. The good disposition manifested by the Blackfoot tribes during the recent disturbances has displayed their natural character, and has been a fact of the utmost value to the welfare of the new settlements.

Since the general peace was established by the American Government the numbers of the Blackfeet have apparently been on the increase. Dr. Hayden reports the three proper Blackfeet tribes as numbering in 1855 about 7,000 souls. The present population of the three Canadian Reserves is computed at about 6,000, divided as follows: Blackfeet proper, 2,400; Bloods, 2,800; Piegans, 800. On the American Reservation there are stated to be about 2,300, mostly Piegans. This would make the total population of the three tribes exceed 8,000 souls. The adopted tribe, the Sarcees, have greatly diminished in numbers through the ravages of the small-pox. In 1870 this disease raged among them with great virulence. They were then residing on the American side, in Montana. Mr. McLean writes: 'An eye-witness told me that at the

Maria's River, in Montana, there stood fully one hundred lodges, and not one contained less than ten bodies. His estimate of dead Sarcees was 1,500.' This tribe, now numbering less than 500 souls, have their Reserve near Calgary. They are reputed to be less cleanly and moral than the proper Blackfeet tribes. In this respect their habits and character correspond with those of other Athabascan tribes.

During the past five years, as is well known, a great change has taken place in the condition of the north-western tribes through the extermination of the buffalo. The transcontinental railways have brought into the interior great numbers of hunters, armed with the most destructive weapons, who have engaged in a constant and reckless slaughter of these animals, until it is now doubtful if any are left alive. The Blackfeet have been the greatest sufferers from this cause. The buffalo were their main dependence. The animals, which roamed the plains during the summer, were accustomed to resort to the sheltered and wooded valleys of the Blackfoot country during the winter; and thus the tribes were assured of a supply of food at all seasons. The skins furnished their clothing, their tents, and their couches. Suddenly, almost without warning, they found themselves stripped of nearly every necessary of life. The change was one of the greatest that could well befall a community. If the inhabitants of an English parish were suddenly transported to the centre of Australia, and set down there, utterly destitute, to make a living by some unknown methods of tropical agriculture, they would hardly be more helpless and bewildered than these unfortunate Indians found themselves. The Governments both of the United States and of Canada came to the rescue; but in the former country the urgency of the case was not at first fully understood, and much suffering ensued. The agent on the Blackfoot Reservation in Montana (Major Allen) states in his official report that when he entered upon his duties in April 1884 he found the Indians in a deplorable condition. The supplies of food which had been sent for them had proved insufficient, and before these could be renewed many died from actual starvation. Some stripped the bark from the saplings which grew along their creeks, and ate the inner portion to stifle the sense of hunger. On the Canadian side, fortunately, the emergency was better understood. Colonel McLeod, an able and vigilant officer, was in charge of the Mounted Police at that time, and through his forethought the necessary preparations were made. In 1879 and 1880 the buffalo disappeared from that region. Arrangements were at once made for settling the Indians on Reserves, and for supplying them with food and clothing, and teaching them to erect wooden houses and cultivate their lands. Daily rations of meat and flour were served out to them. Ploughs, cattle, and horses were furnished to them. Farm instructors were placed among them. The Indians displayed a remarkable readiness to adapt themselves to the new conditions. According to the reports of all the agents they have evinced a quickness to learn and a persevering industry which place them decidedly in advance of the other Indian tribes of that region. In 1882 more than 500,000 lbs. of potatoes were raised by the three Blackfoot tribes, besides considerable quantities of oats, barley, and turnips. The Piegans had sold 1,000 dollars' worth of potatoes, and had a large supply on hand. 'The manner in which the Indians have worked,' writes the agent, 'is really astonishing, as is the interest they have taken, and are taking, in farming.' Axes and other tools were distributed among them,

and were put to good use. In November 1882 the agent writes that log-houses had 'gone up thick and fast on the Reserves, and were most creditable to the builders.' In many cases the logs were hewn, and in nearly all the houses fireplaces were built. In the same year another official—the Indian Commissioner—going through the Reserves, was surprised at the progress which he saw. He found comfortable dwellings, well-cultivated gardens, and good supplies of potatoes in root-houses. Most of the families had cooking stoves, for which they had sometimes paid as much as fifty dollars. He 'saw many signs of civilisation, such as cups and saucers, knives and forks, coal-oil lamps, and tables; and several of the women were baking excellent bread and performing other cooking operations.' Three years before these Indians were wild nomads, who lived in skin tents, hunted the buffalo, and had probably never seen a plough or an axe. These facts are recorded, not merely as gratifying to a sense of humanity, but for their bearing on the question of the natural capacity of uncivilised men. Impartial investigation and comparison will probably show that, while some of the aboriginal communities of the American continent are low in the scale of intellect, others are equal in natural capacity, and possibly superior, to the highest of the Indo-European nations. The fundamental importance of this fact (if such it is) to the science of anthropology must be the excuse for urging its consideration in connection with the present inquiry.

The Blackfeet have been known to the whites for about a century, and during that period have dwelt in or near their present abode. There is evidence, however, that they once lived further east than at present. The explorer Mackenzie, in 1789, found them holding the south branch of the Saskatchewan, from its source to its junction with the north branch. He speaks of four tribes—the Picaneux, Blood, and Blackfeet, and the Fall Indians (Atsinas), which latter tribe then numbered about 700 warriors. Of the three former tribes he says: 'They are a distinct people, speak a language of their own, and, I have reason to think, are travelling north-west, as well as the others just mentioned (the Atsinas); nor have I heard of any Indians with whose language that which they speak has any affinity.'

The result of Mr. McLean's inquiries confirms this opinion of the westward movement of these Indians in comparatively recent times. 'The former home of these people,' he writes, 'was in the Red River country, where, from the nature of the soil which blackened their moccasins, they were called Blackfeet.' This, it should be stated, is the exact meaning of *Siksika*, from *siksinam*, black; and *ka*, the root of *oqkatsh*, foot. The meaning of the other tribal names, *Kena* and *Piekanè*, is unknown. That they were once significant cannot be doubted, but the natives are now unable to explain them, and use them merely as appellatives.

The westward movement of the Blackfeet has probably been due to the pressure of the Crees upon them. The Crees, according to their own tradition, originally dwelt far east of the Red River, in Labrador and about Hudson's Bay. They have gradually advanced westward to the inviting plains along the Red River and the Saskatchewan, pushing the prior occupants before them by the sheer force of numbers. This will explain the deadly hostility which has always existed between the Crees and the Blackfeet.

It will seem, at first view, a perplexing circumstance that M. Lacombe, who, of all authorities, should be the best informed on this subject, and

who has himself recorded this westward movement of the Crees, is disposed to question the fact of the corresponding movement of the Blackfeet. In his last letter, in reply to my inquiries, he expresses a doubt as to their former sojourn in the Red River region, and adds : 'They affirm, on the contrary, that they came from the south-west, across the mountains—that is, from the direction of Oregon and Washington Territory. There were' (he adds) 'bloody contests between the Blackfeet and the Nez-percés, as Bancroft relates, for the right of hunting on the eastern slope of the Rocky Mountains.' Mr. McLean, who mentions the former residence of the Blackfeet in the Red River country as an undoubted fact, also says in the same letter, 'It is supposed that the great ancestor of the Blackfeet came across the mountains.'

Here are two distinct and apparently conflicting traditions, each having good authority and evidence in its favour. One of the best tests of the truth of tradition is to be found in language. Applying this test in the present instance, we are led to some interesting conclusions. It has been seen that Mackenzie, to whom we owe our first knowledge of the Blackfoot tribes, declared that their language had no affinity with that of any other Indians whom he knew of. He was well acquainted with the Crees and Ojibways, who speak dialects of the great Algonkin stock, but he recognised no connection between their speech and that of the Blackfeet. Another traveller (Umfreville), whose book was published in 1791, gave a list of forty-four words of the Blackfoot language. The distinguished philologist Albert Gallatin, whose great work, the 'Synopsis of the Indian Tribes' (which still remains the best authority on North American philology), appeared in 1836, examined this list of Umfreville, and pronounced it sufficient to show that the language of the Blackfeet was 'different from any other known to us.' A few years later he received from an Indian trader a more extended vocabulary, and he then, in a second memoir on the subject, corrected his former statement, and showed that there was a clear affinity between the Blackfoot speech and the language of the Algonkin family. More recently the French missionaries made the same discovery, which seems to have been to them equally unexpected. M. Lacombe writes to me: 'The Blackfoot language, although far from, belongs to the same family as the Algic, Ojibway, Sauteux, Maskegon, and Cree. We discovered this analogy by studying the grammatical rules of these languages.'

Here will be noticed the rather remarkable fact that some of the ablest and most experienced of North American linguists have at first supposed the Blackfoot language to be distinct from all others, and have only discovered its connection with the Algonkin family by careful study. M. Lacombe has been good enough to send me a pretty extensive vocabulary of Blackfoot words, compared with the corresponding words in the Cree and Ojibway languages. He has added what, for the purpose in view, is equally important—many paradigms of grammatical forms in the Blackfoot, compared with similar forms in the Cree and Ojibway tongues. The Blackfoot language is thus shown to be, in its grammar, purely Algonkin. The resemblance is complete in the minutest forms, and in examining these alone it would seem incomprehensible that any doubt of the connection of this language with that stock could have been entertained. But when we turn to the vocabulary, by which the first judgment of a language is necessarily formed, the origin of the early error becomes apparent. Many of the most common words are totally different

from the corresponding words in the Algonkin languages. Others, which are found on careful examination to be radically the same as the corresponding Algonkin terms, are yet so changed and distorted that the resemblance is not at first apparent. Of this variation and distortion the numerals afford a good example. It should be mentioned that in the Indian words which follow, the vowels are to be pronounced as in Italian or German, and the consonants generally as in English. The only peculiarities are in the *j*, which has the French sound (like *z* in *azure*), and the *q*, which I have employed to express a sound resembling the German guttural *ch*, as heard in *lachen*. Mr. McLean writes this sound with *ch*, as in German, and M. Lacombe with *r*. It seems to be a trilled guttural, approaching the sound which French philologists designate as the *r* grasseyé.

	Blackfoot	Cree	Ojibway
One	nitokiskam	peyak	pejik
two	natokam	nijo	nij
three	newowiskam	nisto	nisswi
four	nijoim	newo	niwin
five	nijitji	niyanan	nanan
six	nawo	ningotwasik	ningotwasswi
seven	ikitchike	tepakoup	nijwasswi
eight	nanisho	ayenanew	nishwasswi
nine	pikkiso	kekamitatat	jangasswi
ten	kepo	mitatat	mitaswi
twenty	najippo	nijtano	nijtana
thirty	neppo	nistomitano	nissimitana
one hundred	kepippo	mitatato-mitano	ningotwak

Other words in ordinary use will show the total unlikeness in some cases, and the distorted resemblance in others:—

	Blackfoot	Cree	Ojibway
God	omakkatose	kije-manito	kije-manito
heaven	spoutch	kitchi kijik	kitchi kijik
day	kristikoy	kijikaw	kijikat
night	kokoy	tibiskaw	tibikkat
man	matapi	ayisiyiniw	anisinabe
woman	akew	iskwew	ikkwe
boy	saqkomapi	napesis	kwiwisens
girl	akekowan	iskwesis	ikkwesens
sun	natous	pisim	gisis
earth	tchaqkoum	askiy	akki
water	oqki	nipiy	nipi
fire	tchi	iskoutew	iskoutew
river	niyetaqkay	sipiy	sipi
lake	omaxikimi	sakahigan	sakahigan
house	napi-oyis	waskahigan	wakkahigan
knife	stowan	mokkouman	mokkouman
kettle	iska	askik	akik
tree	mistis	mistek	mittik
my father	n'inna	n'ottawiy	n'oss
my mother	nikrista	ningawiy	ninge
my son	n'oqkowa	nikosis	nigwis
my daughter	nit'ana	nit'anis	nind'anis
my head	n'otokan	n'istikwan	n'istigwan
my mouth	n'ahoy	n'int-on	nind-on
my teeth	n'orpikisth	nipita	nipita
my skin	n'otokis	n'asakay	ninjagai
my tongue	n'atchini	nit'eyaniy	nin'tenani
my heart	n'oskitchipappi	ni-teh	ni-teh
my blood	n'ahaban	ni-mik	ni-mik
my leg	n'oqkat	n'iskat	nikat

No one who examines this list will wonder that the connection between the Blackfoot and the other Algonkin tongues was not apparent to those who had to judge from brief and rude vocabularies of the former language. But it will be noticed that the possessive pronoun 'my' is evidently expressed by the same prefix *ni* (or *n'*) in all three languages. Pursuing this trace we compare the personal pronouns, and find a close resemblance, the difference being mainly in the terminations:—

	Blackfoot	Cree	Ojibway
I	nistowa	niya	nin
thou	kistowa	kiya	kin
he	oustoye	wiya	win
we	nistoninan	niyanan	ninawind
ye	kistowawa	kiyawa	kinawa
they	oustowawa	wiyawa	winawa

In the possessive prefixes the resemblance is still more notable. Thus in the Blackfoot language *n'otas* means 'my horse, or dog' (the same word, oddly enough, applying in this form to both animals); and in Cree *n't'em* has the same meaning. These words are thus varied with the possessive pronouns and in the two numbers:—

	Blackfoot	Cree
My horse (or dog)	n'otas	n't'em
thy " "	k'otas	kit'em
his " "	otas	otema
our " "	n'otasinan	n't'eminan
your " "	k'otasinan	kitemiwaw
their " "	otasiwaw	otemiwawa
my horses (or dogs)	n'otasiks	n't'emak
thy " "	k'otasiks	kit'emak
his " "	otasiks	otema
our " "	notasinaniks	n't'eminanak
your " "	kotasiwaweks	kitemiwawok
their " "	otasiwaweks	otemiwawa

So we may compare *n'inna*, my father, in Blackfoot, with *n'oss*, my father, in Ojibway.

	Blackfoot	Ojibway
My father	n'inna	n'oss
thy "	k'inna	k'oss
his "	ounni	ossan
our "	n'innan	n'ossinan
your "	kinnawaw	k'ossiwa
their "	onniwaw	ossiwan
my fathers	n'innaeks	nossag
thy "	k'innaeks	kossag
his "	ounnieks	ossan
our "	n'innaniks	n'ossinanig
your "	kinnaweks	k'ossiwag
their "	ounniwaweks	ossiwan

It will be seen that the close resemblance in grammar is as striking as the wide difference in the vocabulary. These facts admit of but one explanation. They are the precise phenomena to which we are accustomed in the case of mixed languages. In such languages—of which our English speech is a notable example—we expect the grammar to be derived entirely from one source, while the words will be drawn from two or more. Furthermore, wherever we find a mixed language we infer a conquest of one people by another. In the present instance we may well suppose that when the Blackfoot tribes were forced westward from the

Red River country to the foot of the Rocky Mountains, they did not find their new abode uninhabited. It is probable enough that the people whom they found in possession had come through the passes from the country west of those mountains. If these people were overcome by the Blackfeet, and their women taken as wives by the conquerors, two results would be likely to follow. In the first place, the language would become a mixed speech, in grammar purely Algonkin, but in the vocabulary largely recruited from the speech of the conquered tribe. A change in the character of the amalgamated people would also take place. The result of this change might be better inferred if we knew the characteristics of both the constituent races. But it may be said that a frequent, if not a general, result of such a mixture of races is the production of a people of superior intelligence and force of character.

The circumstances thus suggested may account, not only for the peculiarities of the language and character of the Blackfeet tribes, but also for the different traditions which are found among them in regard to their origin and former abode. It would be very desirable to trace that portion of the Blackfoot vocabulary which is not of Algonkin origin to its source in the language of some other linguistic stock. To do this would require a careful comparison of this foreign element with the various languages spoken in their vicinity, and particularly with those of the tribes west of the Rocky Mountains. For such a comparison there has been neither time nor adequate material, and this interesting subject of inquiry must be left for another occasion.

The religion of these tribes (applying this term to their combined mythology and worship) resembles their language. It is in the main Algonkin, but includes some beliefs and ceremonies derived from some other source. Father Lacombe's account of their cosmogony and their deities cannot be better given than in his own clear and pithy style. In their view, as in that of the Lenape and other Algonkin nations, there were two creations: the primary, which called the world into existence, and of which they have but a vague idea; and the secondary, which found the world an expanse of sea and sky (with, it would seem, a few animals disporting themselves therein), and left it in its present state. 'The primitive creation,' writes M. Lacombe, 'is attributed to a superior divinity, whom they call the Creator (*Apistotokiw*). This divinity, however, is in some manner identified with the sun (*Natōs*). The earth itself is believed to be a divinity of some kind, for, in their invocations, if they call the sun "our father" (*Kinnon*), they call the earth "our mother" (*Kikristonnon*). It seems also that the moon is considered to be one and the same divinity with the sun. At any rate, in the invocations it is designated by the same name, *Natōs*. Yet it is often said to be the "old woman," the consort of the sun. The whole of this is confused enough in the minds of the Indians to render them unable to give, when questioned, exact explanations.

'As to the secondary creation, if it may be so styled, the Indian account runs as follows: At a certain time it happened that all the earth was covered with water. The "Old Man" (*Napiw*) was in a canoe, and he thought of causing the earth to come up from the abyss. To put his project into execution he used the aid of four animals—the duck, the otter, the badger, and the musk-rat. The musk-rat proved to be the best diver. He remained so long under water that when he came to the surface he was fainting, but he had succeeded in getting a little particle of earth, which he brought between the toes of his paw. This particle of earth

the "Old Man" took, and blowing on it he swelled it to such an extent as to make the whole earth of it. Then it took him four days to complete his work, and make the mountains, rivers, plants, and beasts. (This number *four* is a fatidical one in the legends of these Indians.) The "Old Man" worked two days more in order to make the first woman, for after the first day's work he had not succeeded in making anything graceful. When the first woman, after much toil, was completed, a sort of council was held, in which the woman opposed every one of Napiw's propositions that would have been very favourable to the welfare of mankind. So we must conclude that all the evil on the earth comes from the woman's contradictious will.'

This Napiw, or 'Old Man,' adds Father Lacombe, 'appears again in many other traditions and legendary accounts, in which he is associated with the various kinds of animals, speaking to them, making use of them, and especially cheating them, and playing every kind of trick. In these legends Napiw comes down from the high position of creator to a much lower one, and appears not unlike to a buffoon and treacherous rascal. I will mention only that, according to the account of the Indians, the "Old Man" is said to have come from the south-west, across the mountains; and after a prolonged sojourn in these countries he went toward the north-east, where he disappeared, and nobody has heard of him since. The Indians point out the place where the "Old Man" played with the Coutonay Indians, not far from the Porcupine Hills; on another spot he slept; and on a hill not far from Red-deer River any one can see at the present day the place where Napiw came down by sliding.'

Those who have read Schoolcraft's 'Algic Researches,' Mr. Leland's 'Algonquin Legends,' and, above all, Dr. Brinton's 'Myths of the New World,' will recognise in Napiw the most genuine and characteristic of all the Algonkin divinities. In every tribe of this widespread family, from Nova Scotia to Virginia, and from the Delaware to the Rocky Mountains, he reappears under various names—Manabosho, Michabo, Wetuks, Glooskap, Wisaketjak, Napiw—but everywhere with the same traits and the same history. He is at once a creator, a defender, a teacher, and at the same time a conqueror, a robber, and a deceiver. But the robbery and deceit, it would seem, are usually for some good purpose. He preserves mankind from their enemies, and uses the arts and craft of these enemies to subdue and destroy them. In Dr. Brinton's view, his origin is to be found in a nature-myth, representing, 'on the one hand, the unceasing struggle of day with night, of light with darkness, and, on the other, that no less important conflict which is ever waging between the storm and sunshine, the winter and summer, the rain and clear sky.'

Napiw, the 'old man,' has, it seems, other names in the Blackfoot tongue. He is known as *Kenakakatsis*, 'he who wears a wolfskin robe,' and *Mik-orkayew*, 'he who wears a red-painted buffalo-robe.' These names have probably some reference to legends of which he is the hero. The name of the creator, *Apistotokiw*, as explained by M. Lacombe, offers a good example of the subtle grammatical distinctions which abound in the Siksika (or Blackfoot) speech, as in the other Algonkin tongues. The expression 'he makes,' or 'he creates' (which, like other verbal forms, may be used as a noun), can be rendered in four different forms. *Apistototsim* signifies 'he makes,' when the complement, or thing made, is expressed, and is an inanimate object. *Apistotoyew* is used when the expressed object is animate. *Apistotakiw* is the indefinite form, used

when the complement, or thing made, is not expressed, but is understood to be inanimate; and, finally, *Apistotokiw*, the word in question, is employed when the unexpressed object is supposed to be animate. The world, therefore, as first created, was, in the view of the Blackfoot cosmologist, an animated existence.

But while these beliefs are all purely Algonkin, the chief religious ceremony of the Blackfoot tribes is certainly of foreign origin. This is the famous 'sun-dance,' to which they, like the Dakota tribes and some of the western Crees, are fanatically devoted. That this ceremony is not properly Algonkin is clearly shown by the fact that among the tribes of that stock, with the sole exception of the Blackfeet and a few of the western Crees, it is unknown. Neither the Ojibways of the lakes nor any of the numerous tribes east of the Mississippi had in their worship a trace of this extraordinary rite. The late esteemed missionary among the Dakotas, the Rev. Stephen R. Riggs (author of the 'Dakota Grammar and Dictionary') says of this ceremony: 'The highest form of sacrifice is *self-immolation*. It exists in the "sun-dance," and in what is called "vision-seeking." Some, passing a knife under the muscles of the breast and arms, attach cords thereto, which are fastened at the other end to the top of a tall pole, raised for the purpose; and thus they hang suspended only by those cords, without food or drink, for two, three, or four days, gazing upon vacancy, their minds intently fixed upon the object in which they wish to be assisted by the deity, and waiting for a vision from above. Others, making incisions in the back, have attached, by hair-ropes, one or more buffalo-heads, so that every time the body moves in the dance a jerk is given to the buffalo-heads behind. This rite exists at present among the western bands of the Dakotas in the greatest degree of barbarity. After making the cuttings in the arms, breast, or back, wooden setons—sticks about the size of a lead-pencil—are inserted, and the ropes are attached to them. Then, swinging on the ropes, they pull until the setons are pulled out with the flesh and tendons; or, if hung with the buffalo-heads, the pulling-out is done in the dance by the jerking motion, keeping time with the music, while the head and body, in an attitude of supplication, face the sun, and the eye is unflinchingly fixed upon it.'

My correspondent, the Rev. Mr. McLean, sends me a minute and graphic account of this ceremony as he witnessed it, in June last, on one of the Blackfoot Reserves, when most of the Kena, or Blood Indians, were present as actors or spectators. His narrative is too long for insertion here in full, but the concluding portion will show the resolute constancy with which this sacrifice of self-immolation is performed—some new features being added, which are not found in the brief account of Mr. Riggs, though they may possibly belong also to the Dakota ceremony.

'This year several persons, young and old, who had made vows during times of sickness or danger, had a finger cut off by the first joint, as an offering to the sun; and others had the operation of cutting their breasts and backs. The old woman who cut the fingers off held the suppliant's hand up to the sun, and prayed; then placed it upon a pole on the ground, laid a knife on the finger, and with a blow from a deer's-horn scraper severed the member. The severed piece was taken up, held toward the sun, and the prayer made, when it was dropped into a bag containing similar members. This ceremony was gone through by each in turn. After this was done each carried an offering, and,

climbing the sacrificial pole with the face reverently turned toward the sun, placed the offering on the top of the pole. This year seven or eight persons went through the above ceremony. The other sacrificial ceremony consisted of the slitting of the flesh in two pieces in each breast. A wooden skewer was placed through each breast; a rope fastened to the sacrificial pole was placed around each skewer; and then the suppliant, whistling upon the bone-whistle, jumped about until the flesh gave way. In some instances the flesh was cut so deeply that the men had to press heavily upon the performers' shoulders in order to tear it away. The "shield ceremony" was the same process, only performed on the back, and the rope with a shield attached fastened to the skewers, and the ceremony continued until the suppliant was relieved.'

Mr. Riggs, it will be noticed, says that the ceremony was most zealously performed among the most westerly of the Dakota tribes, that is, those which are nearest to the Rocky Mountains. We are thus led to suppose that it may have had its origin among the tribes west of the mountains. Possibly the Blackfeet may have learned it from the tribe from which they acquired the foreign element of their language, and they may have taught it to the western Dakotas and Crees in their neighbourhood. In any case it is clear that they have a mixed religion, as well as a mixed language—which are both facts of considerable interest in ethnological science.

The form of government among the Blackfeet, as among the Algonkin tribes generally, is exceedingly simple, offering a striking contrast to the elaborately complicated systems common among the nations of the Iroquois stock. Each tribe has a head-chief, and each band of which the tribe is composed has its subordinate chief; but the authority of these chiefs is little more than nominal. The office is not hereditary. The bravest or richest are commonly chosen; but in what manner the election is made is not stated. Formerly the principal function of the head-chief consisted in deciding on the question of peace or war. At present it is limited to fixing the place of the camp, or directing a change of encampment. He presides in the council of his tribe, and is, in a conference with other nations, the representative and spokesman of his people.

The term 'confederacy' commonly applied to the union of the Blackfoot tribes is somewhat misleading. There is no regular league or constitution binding them together. 'The tribes are separate,' writes Mr. McLean, 'and the bonds of union are the unity of religious belief, social customs, and language. They united against a common enemy, but I have never heard of their fighting against each other.' Father Lacombe's account is similar. 'The Blackfeet,' he writes, 'have no league or confederation, properly so called, with councils and periodical reunions. They consider themselves as forming one family, whose three branches or bands are descended from three brothers. This bond of kinship is sufficient to preserve a good understanding among them.' They can hardly be said to have a general name for the whole community, though they sometimes speak of themselves as *Sawketakix*, or 'men of the plains,' and occasionally as *Netsepoyè*, 'or people who speak one language.'

Whether the system of clans, gentes, or totems, as they are variously styled by different writers, is found among the Blackfoot tribes is uncertain, the replies to inquiries on that subject being thus far somewhat indefinite. This system is regarded by some eminent ethnologists

as one of general prevalence, marking a certain stage in the progress of society. Others consider it to be merely a special and local manifestation of the associative impulse, frequently important, but by no means universal or essential in any stage. The fact that, while it prevails among the Iroquois, the Dakotas, and the Ojibways, it is not found among the Crees or the tribes of Oregon, seems to lend countenance to this view, and gives, at all events, particular interest to the inquiry in the present case. This and other questions remain for future investigation. For the reasons which have been stated, the present report is unavoidably imperfect. It is offered chiefly for the purpose of preserving the information which has already been obtained from sources of the highest authority, and of thus affording a trustworthy basis for further inquiry.

Report to the Council of the Corresponding Societies Committee, consisting of Mr. FRANCIS GALTON (*Chairman*), Professor A. W. WILLIAMSON, Captain DOUGLAS GALTON, Professor BOYD DAWKINS, Sir RAWSON RAWSON, Dr. GARSON, Dr. J. EVANS, Mr. J. HOPKINSON, Professor MELDOLA (*Secretary*), Mr. WHITAKER, Mr. G. J. SYMONS, *and* Mr. H. GEORGE FORDHAM.

THE Corresponding Societies Committee beg to report that they have received and considered applications from fifty-two Societies, and they recommend that those of the thirty-nine whose names are entered in the accompanying list be granted.

The Committee in making their selection have interpreted the phrase 'local scientific investigation,' which occurs in the new Rules (see Report 1884, pp. lxv. and lxvi.), according to the tenor of the examples they gave of such work in the Report 1883, p. 319, taken from among the subjects of inquiry assigned to Committees of the Association during the past five years, and rearranged as follows, in the order of the Sections that are now severally concerned in them :—(A) Luminous meteors; meteoric dust in various localities; rainfall; underground temperature. (C) Erosion of sea-coasts; height of underground waters; erratic blocks. (D) Migration of birds at lighthouses and lightships; periodical natural phenomena (flowering of plants, &c.); injurious insects (their first appearance, &c.). (F) Working of Education Code in elementary schools; rudimentary science in schools. (G) Effective wind-pressure on buildings. (H) Photographs of typical races and crosses; ancient earthworks; prehistoric remains; anthropometric collections.

They have placed only one Society (the Liverpool Astronomical Society) on the selected list which published no results of local scientific investigation during the past year; they have included it, and some others whose publications of that description were few, on account of their general scientific activity and influence.

Two Societies—the Inverness Scientific Society and the Isle of Man Natural History and Antiquarian Society—have been included in the selected list, and the titles of the papers furnished by their secretaries, as read before them in 1884, have on this occasion been catalogued, although the publications have not yet been received. It is proposed that for the future Rule 5 be strictly adhered to.

The Committee are glad to find that the Societies they have selected prove to be evenly distributed throughout the United Kingdom.

SELECTED LIST

OF SOCIETIES RECOMMENDED BY THE CORRESPONDING SOCIETIES COMMITTEE FOR ELECTION AS

Corresponding Societies of the British Association.

Title of Society	Abbreviated Title	Index No.
Aberdeen Natural History Society . . .	Aberdeen N. H. Soc.	1
Barnsley Naturalists' Society	Barns. Nat. Soc.	2
Bath Natural History and Antiquarian Field Club .	Bath N. H. A. F. C.	3
Belfast Naturalists' Field Club	Belfast Nat. F. C.	4
Birmingham Natural History and Microscopical Society	Birm. N. H. M. Soc.	5
Birmingham Philosophical Society . . .	Birm. Phil. Soc.	6
Burton-on-Trent Natural History and Archæological Society	Burt. N. H. Arch. Soc.	7
Cambridge Philosophical Society	Camb. Phil. Soc.	8
Cardiff Naturalists' Society	Cardiff Nat. Soc.	9
Cornwall, Mining Institute of	Cornw. Min. Inst.	10
Cornwall, Royal Geological Society of . . .	Cornw. R. Geol. Soc.	11
Cumberland and Westmoreland Association for the Advancement of Literature and Science .	Cumb. West. Assoc.	12
Dumfriesshire and Galloway Scientific, Natural History, and Antiquarian Society . . .	Dum. Gal. Sci. N. H. Soc.	13
East of Scotland Union of Naturalists' Societies .	E. Scot. Union	14
Edinburgh Geological Society	Edinb. Geol. Soc.	15
Essex Field Club	Essex F. C.	16
Glasgow, Geological Society of	Glasgow Geol. Soc.	17
Glasgow, Natural History Society of . . .	Glasgow N. H. Soc.	18
Hertfordshire Natural History Society and Field Club	Herts. N. H. Soc.	19
Holmesdale Natural History Club . . .	Holmesdale N. H. C.	20
Inverness Scientific Society and Field Club . .	Inverness Sci. Soc.	21
Liverpool Astronomical Society	Liv'pool Ast. Soc.	22
Liverpool Engineering Society	Liv'pool E. Soc.	23
Liverpool Geological Society	Liv'pool Geol. Soc.	24
Liverpool, Literary and Philosophical Society of .	Liv'pool Lit. Ph. Soc.	25
Manchester Geological Society	Manch. Geol. Soc.	26

SELECTED LIST OF SOCIETIES—*continued.*

Title of Society	Abbreviated Title	Index No.
Man, Isle of, Natural History and Antiquarian Society	I. of Man N. H. A. Soc.	27
Marlborough College Natural History Society .	Marlb. Coll. N. H. Soc.	28
Midland Union of Natural History Societies .	Mid. Union	29
North of England Institute of Mining and Mechanical Engineers	N. Eng. Inst.	30
North Staffordshire Naturalists' Field Club and Archæological Society	N. Staf. N. F. C. A. Soc.	31
Northamptonshire Natural History Society and Field Club	N'ton. N. H. Soc.	32
Perthshire Society of Natural Science . . .	Perths. Soc. N. Sci.	33
Rochester Naturalists' Club	Rochester N. C.	34
Scottish Geographical Society	Scot. Geog. Soc.	35
South African Philosophical Society	S. African Phil. Soc.	36
Warwickshire Naturalists' and Archæologists' Field Club	Warw. N. A. F. C.	37
Yorkshire Geological and Polytechnic Society .	Yorks. Geol. Poly. Soc.	38
Yorkshire Naturalists' Union	Yorks. Nat. Union	39

Index of Papers referring to Local Scientific Investigations published during the Past Year by the above-named Societies.

Section A.—MATHEMATICAL AND PHYSICAL SCIENCE.

On Electrolysis. By Professor OLIVER J. LODGE, *D.Sc.*

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

WHEN in response to an urgent request by the President of Section B I agreed to open the present discussion, it was only after a good deal of hesitation that I consented. For though convinced of the immense importance of a more thorough study of the facts and phenomena connected with the passage of electricity through decomposable bodies, and of its vital interest to all scientific chemists, yet it was not a subject that I had made specially my own; having been in fact to a great extent deterred by the immense area it covered, and by the somewhat repulsive character attaching to any borderland branch of science—in this case not wholly physics nor wholly chemistry—a repulsiveness perhaps only subjective, and probably to be attributed to a feeling of incapacity for grasping both aspects of the subject with equal completeness. This difficulty still remains with me, and though I have made a severe attempt to tackle the subject as best I could during the past month, I have been quite unable to cover the immense field, or to read more than the summaries of its literature; and accordingly I shall attempt no historical or chronological survey, but shall endeavour simply to direct attention to certain theoretical points which are undoubtedly of interest and importance, and to suggest the answers which I myself feel inclined to give to debatable questions which bristle round even the most elementary facts; in the hope that, attention being thus directed to them, success in finally solving some of them may be attained by a more competent hand.

Naturally I confine myself to the more physical aspect of the subject, because, my chemical knowledge being of a meagre and antiquated description, it is better worth your while that I should attempt reasonably good physics than that I should perpetrate unreasonably bad chemistry.

Moreover no chemical development will be satisfactory and permanent unless erected on a thorough physical basis; and, if I may venture an opinion on such a subject, I believe that the work of a few chemical philosophers spent in broadening and deepening the foundations of their science would soon confer upon the superstructure a less unsightly and lopsided appearance than, seen from outside, it at present has.

The first question which presents itself is—

I. WHAT IS AN ELECTROLYTE ?

The question may have either of two distinct meanings—

(*a*) Is a substance an electrolyte at all; *i.e.*, when alone ?
(*b*) Is it the electrolyte in any particular case; *i.e.*, when mixed with other substances ?

First meaning of I.

As answers to (*a*) certain chemical statements have been made, such as: 'all electrolytes are compounds of a metal with a non-metal' (Miller);

'electrolytes are either simple binary compounds, or are capable of being formed from them by double decomposition, the ions being the radicles so exchanged' (Wiedemann); &c. Such statements may be true, and if true may be important chemical generalisations, but they are not physical definitions or tests of electrolytic conductivity.

As a physical definition of an electrolyte we have only to say, *an electrolyte is a substance which conducts electrolytically.*

A statement like this only helps by fixing our attention on the real point in question, viz. the difference between electrolytic and metallic conduction—a true physical distinction, which is capable of definite examination, and may be capable of precise statement.

Whether we are able thus sharply to divide off electrolytes from other conductors will depend on whether any substance be found which can conduct both like a metal and like an electrolyte. Such a substance is not yet, I believe, certainly known, though it has been often suspected; it has even been suspected that all electrolytes have a trace of metallic conductivity. Though for the present this is quite unproved, and may be regarded as against the weight of evidence, it would be rash to insert the word *wholly* into the above definition; it must be left as meaning that *in so far* as a body conducts electrolytically, so far it is an electrolyte.

Now electrolytic conduction differs from metallic conduction in several ways. Metallic conduction appears to be a true passage of electricity through matter; it is unaccompanied by any reversible or chemical process, it simply generates heat.

Electrolytic conduction is accompanied by certain reversible chemical processes, and appears to be of the nature of a convection of electricity by the atoms of matter.

A substance which so conducts is an electrolyte, and whether it be a good or a bad conductor is foreign to the inquiry.

It is important to notice this because it is often sought to deny that (say) water is an electrolyte by showing that it is a bad conductor. Of course if it *does not conduct at all* it is no electrolyte, but a dielectric. Our definition says first that an electrolyte must conduct, and it then proceeds to say how it must conduct.

Water, alcohol, turpentine, glass, either conduct a little or they do not. If they do not, they are dielectrics pure and simple; but experiments on leaks have always shown a more rapid leak if water, alcohol, or turpentine be used to replace air; and as to some kinds of glass, it seems to be a mere question of temperature whether they conduct or not. If it be proved that any of these things, even when pure, conduct, be it ever so badly, they are not simple dielectrics, and it remains only to consider whether their conduction is metallic or electrolytic.

But it may happen that some of these bodies, or *perhaps* all liquids, behave as dielectrics to rapidly intermittent or alternating E.M.F.s, but as electrolytes to slow and long-continued E.M.F.; just as pitch is elastic to rapid vibrations (it can transmit sound for instance), but is viscous and essentially fluid to long-continued forces. Whether this is so or not is a vital question in relation to the electromagnetic theory of light, wherein the transparency of conducting liquids has only been provisionally and tentatively explained.

Tests for electrolytic conduction as distinct from metallic.

So far as experiment has yet gone, electrolytic conduction is found to obey Ohm's law—a remarkable and important fact, if fact it accurately be—and we will return to it later.

The obedience to Ohm's law shown by electrolytes prevents our drawing any easy and sharp line of demarcation between the two classes of bodies. To distinguish between them we have to study what happens at a boundary or junction of the two classes of conductors.

At such a place Ohm's law utterly breaks down; a finite E.M.F. is needed to drive any permanent current, however small. And the reason is that the atoms which have conveyed the electricity through the electrolyte can accompany it no longer, and have either to give it up and let it go on without them, or cling to it and stop the current. In either case we have what is called polarisation. If the clinging power of the atoms is greater than the applied E.M.F., the current may wholly cease, and as soon as the E.M.F. is removed, will spring back again, the opposition to it being no longer like friction, but like a strained spring.

If the applied E.M.F. overcome the atomic force, the current flows on, leaving the discarded atoms to do what they like. They may combine with each other and separate from the liquid, in which case we have visible chemical decomposition; or they may combine with each other and dissolve in the liquid; or they may combine with the liquid, forming secondary products; or they may combine with the electrodes.

They usually cling tightly to the electrode, even if unable actually to combine with it, and by thus altering its surface they may give rise to a permanent opposite current. The four possibilities are—

Combination with, or solution in, the liquid.
Combination with, or deposition upon, electrodes.
Combination with something already dissolved in liquid.
Combination with each other and freedom.

Wherever visible decomposition occurs, there is no doubt of electrolysis, so that is the most simple and obvious test of electrolytic conduction. But the conductivity may be so bad that no visible product forms in a century. In that case *polarisation*, if present, is a test. As Helmholtz says: 'Galvanometers are sensitive enough to shew a current which could only decompose a milligramme of water in a century.' [1]

But this test also may fail by reason of secondary actions. It is the merest commonplace that an ordinary voltameter behaves as a very leaky condenser. A continual drain of electricity goes through it, however small the E.M.F. applied; and when charged, and left, the charge is found very rapidly to diminish. It is facts like these of course which have so often suggested slight metallic conductivity, and which at one time tempted Faraday to postulate this.

With certain fused salts the decay of polarisation is so rapid that polarisation hardly appears to exist; and quite a strong current can be sent through them without any visible decomposition. Clark [2] has shown that in these cases it is the solution of the liberated ions and their rapid diffusion which causes this apparent metallic conduction. There is pro-

[1] One may notice that even such a current as this is still 10 electrostatic units per second.

[2] J. W. Clark, *Phil. Mag.*, October 1885.

bably a full quota of decomposition, but, unless special precautions are taken, recomposition is just as rapid.

The same thing goes on far more slowly in dilute acid, especially if it contain dissolved gases; and the experiments of Helmholtz with an ingeniously contrived gas-free cell, as related in his Faraday Lecture of 1881, may be taken as settling the quantitative question whether this decay of polarisation is any of it due to slight metallic conduction, or whether the whole of it is rigorously due to solution and diffusion of the semi-liberated ions. It is of course true that these experiments do not settle it for *all* electrolytes, but for dilute sulphuric acid at any rate they prove that the diffusion and indirect recombination of the ions accurately account for everything; and that, when these are stopped a voltameter behaves as a good and non-leaking condenser up to a certain E.M.F., beyond which it conducts with visible decomposition.

It may be as well, perhaps, to avoid misconception by stating that, by the solution and recombination spoken of above, I do not absurdly suppose that nascent O and nascent H, respectively dissolved in the liquid, travel to meet each other and recombine. Upon such direct action as that the presence or absence of dissolved air could have no influence. What one supposes to go on is this. Semi-liberated hydrogen, finding dissolved oxygen in its neighbourhood, combines with it; the corresponding oxygen simultaneously liberated at the other pole dissolves in the liquid, and, so replenishing it, keeps the action continuous at a slow rate regulated by the rapidity of diffusion.

I see nothing, however, to prevent a *liberated* ion from dissolving in the liquid, or from diffusing across to the other electrode, where it may combine with the nascent ion, and so reduce the apparent out-put of the cell; and this action, having nothing to do with dissolved air, might go on even in Helmholtz's gas-free cell. But it could not begin, I imagine, unless the E.M.F. were sufficient to set both ions free;[1] consequently, by never applying more than a feeble E.M.F., this disturbing action may be obviated.

When dissolved oxygen already exists, neither ion has really to be set free; consequently even a feeble E.M.F. is sufficient to maintain a weak current.

In cases where the polarisation test for electrolysis thus fails, Helmholtz proposes another, viz.: *Electrolytes do not fall into Volta's tension series.* An assemblage of metals at constant temperature can give no permanent current: introduce an electrolyte into the series, and they can.

On this principle Helmholtz considers he has proved that the conduction of glass is not metallic; for he makes a Daniell cell with a complete glass partition in place of a porous cell, and finds that the glass does not stop the current by polarisation, as a metal partition would, but that the cell behaves exactly like any other cell with an enormous internal resistance.

One more test, those of us who believe in the electrical theory of light may suggest, viz. *transparency.* A conductor, if transparent, must be an electrolytic conductor. Thus a fused salt, if it be clear and transparent and yet conduct well (as argentic iodide does for instance), may be assumed to be an electrolyte, despite the absence of products of decom-

[1] The E.M.F. required to set an ion free enough to enter into solution is almost enough to set it free altogether. The only difference, I suppose, is *pdv*; and at ordinary pressures this is negligible.

position and of polarisation; unless, of course, rigorous proof can be given that its conduction is metallic, which has in no case happened yet.

Electrolytes seem necessarily fluid, and it is difficult to imagine the locomotion of atoms which accompanies electrolysis to go on in a solid body. Mr. Shelford Bidwell, Dr. Silvanus Thompson and others consider they have found solid electrolytes, but it behoves us to be very careful in accepting such an idea; extreme viscosity there may be, as in hot glass, but not the true rigidity of a solid, unless certain proof is forthcoming.

The tests of electrolytic conduction are these four—

1. Visible decomposition.
2. Polarisation.
3. Non-agreement with Volta's series law.
4. Transparency.

We may thus pretty safely distinguish electrolytes from metals, but to certainly distinguish electrolytes from dielectrics is not always easy. True a dielectric does not conduct, but it may break down. How to distinguish an electrolyte from a *weak* dielectric, as, for instance, rare air: this is not easy. An initial E.M.F. is needed to commence disruptive discharge, but that may be easily confused with electrolytic polarisation of electrodes: indeed some facts suggest that there is a considerable surface or boundary resistance which opposes the passage of electricity from metal into rare air and may altogether stop it when very small terminals are used.

Second meaning of I.

Now pass to the second aspect of the question, what is an electrolyte, viz. (*b*) Is a particular substance *the* electrolyte when mixed with other matter?

If a voltameter had a glass partition with a hole in it, no supporter of the view that glass was an electrolyte would contend that the glass conducted some of the current. Similarly with a water partition, or with any water existing *in a mass* in any part of the vessel. Non-conductivity or bad conductivity has thus everything to say to this question, What is *the* electrolyte?

But then, in a solution of acid or salt water, it is not merely mixed with the substance, it is combined with it; and it is very possible that water in this state may conduct readily enough. Information on this head, sure and definite as it seems to me, is given by the simple fact that pure H_2O and pure liquid HCl both almost insulate when separate, but conduct well enough when mixed.

There are, then, four hypotheses concerning the apportionment of the current among the substances in a salt solution.

(1) That the salt alone conducts.

(2) That the water alone conducts.

(3) That the salt and the water share the conduction between them.

(4) That neither salt nor water exist, but that a hydrate is formed, and that this conducts and is decomposed as a whole.

To decide whether when substances are mixed both conduct the current, Hittorf mixed KCl and KI in various proportions, and concluded that the current always travelled through both salts. Buff has made many similar experiments, and agrees. Gore has deposited brass from a

cyanide solution of copper and zinc. True the combined resistance is not the semi-harmonic mean of the separate resistances, but there is no earthly reason why it should be. It is a mere superstition to expect such a result. Even if the substances were really mixed and not combined, it would not be so; unless there were a boundary surface between the media made wholly of stream-lines, *i.e.* a surface across which no electricity flowed.[1]

Another mode of discriminating between the hypotheses is to use intense currents.[2] For with intense currents you are more likely to get off the real ions: secondary actions are hurried, and cannot go on properly. With intense currents the ions are very apt to come off in a very self-combined and energetic state (as ozone instead of oxygen, &c.), and an extra polarisation force accounts for this extra energy; but they do not so easily combine with other matter in the solution.

Now Magnus showed that from a solution of $CuSO_4$ weak currents deposited copper only, while strong currents liberated hydrogen as well. In fact the observation is now a commonplace. But it is much easier to turn copper out of combination than hydrogen. So if copper were the real primary ion there is no call for hydrogen to appear. It looks therefore as if hydrogen were at least *a* primary ion, and possibly the only one. But then, as pointed out by Smee, local exhaustion of the liquid near the cathode may cause such a deficiency of copper in the liquid touching the plate, that, if the current is too intense for diffusion to keep up the supply, hydrogen must perforce be liberated from the simple acid coating of the cathode. Hence in repeating any experiment of this kind it will be necessary to stir or scour the plate constantly and vigorously; and even then there would be some uncertainty about the matter, supposing hydrogen persistently appeared.

Is there any more direct and simple mode of answering the question as to whether the salt or the water or both conduct the current?

Yes, what seems to me a very simple and satisfactory one; by determining at which pole free acid appears; and, if it appears at both, by determining how much appears at either.

For the sake of clearness it may be well to point this out in detail, though indeed it is so simple as hardly to be necessary.

Consider a solution of copper sulphate in water; decompose it with platinum electrodes, and first make the assumption that the *salt* conducts the whole current, or that the real ions are Cu and SO_4. At the cathode Cu appears and is deposited—nothing else happens. At the anode SO_4 appears, decomposes water, forming sulphuric acid, and setting free oxygen. Thus on this hypothesis all the free acid appears at the *anode*.

Next make the assumption that *water* conducts the whole current, so that hydrogen and oxygen are the true ions. At the anode oxygen appears and is liberated—nothing else happens. At the cathode hydrogen appears, decomposes $CuSO_4$, forming sulphuric acid, and setting free copper. So on this assumption all free acid appears at the *cathode*.

[1] This fact, that no crossflow between 'multiple arc' conductors must occur, if their combined conductivity is to be the sum of their separate conductivities, is sometimes overlooked. The covering on ordinary wires supplies the necessary condition; but if the wires touch the law breaks down. To the parts of one conductor the 'divided circuit law' is by no means necessarily applicable.

[2] Meaning always by 'intensity' of current, *strength of current per unit area*, or what is sometimes inconveniently styled 'density' of current.

Finally, let the water conduct $\frac{1}{x}$th, and the salt $\frac{x-1}{x}$th of the current, then the ratio of the free acid formed at anode to that formed at cathode will be $x-1$.

Now I have made many preliminary experiments; avoiding porous partitions of course, as introducing electric endosmose, capillary forces, and all kinds of unknown disturbances; using only two vessels connected with a syphon U tube, and other such arrangements. I find in all cases acid at *both* poles, though, *with platinum electrodes*, usually most at anode. I do not press these preliminary results; a great deal of easy quantitative work suggests itself in this connection, and it is necessary to specify and to vary the concentration of solution and the strength of current used. The *method* is the important thing, and I should like to have it either approved or condemned.

If one uses copper electrodes, the results are somewhat different. On the hypothesis that the salt alone conducts, no free acid should be formed anywhere; the solution should become impoverished at cathode and concentrated at anode—phenomena which are well known to occur to a greater or less extent. If, on the other hand, the water alone conduct, free acid should appear at cathode but not at anode; the solution near cathode should again become impoverished of copper, though not of SO_4; while upon the anode is liable to form a coat of oxide which there is no sufficient supply of free acid near to dissolve off. And all these phenomena are also found to occur. The deposit of oxide on a copper anode is with intense currents most marked, so much so as almost to stop them. It is most instructive to put some dead-beat instrument like Ayrton and Perry's Ammeter into circuit with a copper voltameter too small for the current, and watch the needle descend from the stops quickly almost to 0.[1] Free acid *does* make its appearance at the cathode —and, with intense currents, plenty of it.

Roughly one may judge perhaps that the salt conducts about three-fourths of the current and the water one-fourth, but I have no certain data yet for any such statement; and the proportion may well vary, for all I know, with the current intensity. One may, however, definitely accept hypothesis 3 or 4 as certainly truer than 1 or 2.

The fact that acid is produced at anode, and alkali at cathode, in the decomposition of, say sodic sulphate, proves that the salt conducts at least some of the current; and an estimation of the amount of acid and alkali respectively generated would decide what proportion was so conducted.

Again, experiments with electrolytes in series, as made by Hisinger, by Berzelius, and by Davy, are interesting in their bearing on this point.[2] Thus, take three vessels containing, say, HCl, HNO_3, and $AgNO_3$; or Na_2SO_4, HCl, and $BaCl_2$, respectively; and the formation of a precipitate is a good identification of a true ion. The *locality* of such precipitate is still more instructive, since it conveys information as to the relative rates at which the opposite ions travel, and so leads us on to the next question, concerning what is called 'the migration of ions.'

[1] Hence, in arranging such voltameters, the anode should be larger than the cathode.

[2] An old experiment of Faraday's (Exp. Res. 494) on the formation of magnesic hydrate at a junction of Epsom salts and water when a current passes, is now accepted, even by Kohlrausch, as proving that water may in some cases conduct.

II. The Migration of Ions.

Do the opposite ions in solutions travel at different rates? And, in any case, at what rate do they travel?

Here, as is well known, we must draw a distinction between fused and dissolved compounds. Fused or homogeneous electrolytes, in which no solution occurs, must always remain of uniform composition; consequently, considering any bounded region, exactly equivalent quantities of either ion must pass out of it on the whole. It is not evident that the two constituents must pass out *in opposite directions*, but in so far as they pass out in the same direction there is no true electrolytic decomposition: there is only a kind of electric endosmose, affecting the level of the fluid as a whole. Given that the level remains uniform, and that ions are only liberated at electrodes, then it is plain that the opposite corresponding ions must pass through any imaginary plane in the fluid at the same rate in opposite directions; for, if not, the constitution of the fluid would not remain uniform.

This argument fails to apply to *dissolved* salts, and it breaks down before long even with fused salts if they dissolve one of the liberated elements or any other body, because *in a solution* no necessity for uniformity of composition exists—one portion may be concentrated, while another is quite weak; and it is well known that such weakening and concentrating actions do occur in electrolysed solutions: *e.g.*, to specify a hackneyed but sufficiently instructive case, in the electrolysis of dilute sulphate of copper with copper electrodes the solution near cathode becomes weaker, while that near anode becomes stronger, than before. If the anode is arranged above the cathode visible blue streaks descend; if the arrangement is inverted the top liquor gets almost clear. If platinum electrodes be used both sides get weaker, but the cathode side weakens two or three times as fast as the anode side. It is customary to explain these well-known and perfectly certain experimental facts by the obvious and plausible hypothesis that the two ions do not travel both at the same rate through the liquid, but that the SO_4 travels quicker than the Cu. Such an explanation accounts for the phenomenon, but it does not follow that it is certainly the true explanation; and for the sake of examining it more particularly I may be allowed to suggest doubts concerning it. If these doubts have no sound physical basis their statement will only result in their removal, and can do no harm.

First let us quickly see how the hypothesis of unequal velocity accounts for the unequal concentration of solution which is called migration. Let SO_4 travel, say, three times as fast as Cu; and consider an imaginary partition about the middle of the cell. Three atoms of SO_4 travel unit distance through it towards the anode for every atom of Cu travelling unit distance in the other direction; but the number of atoms of Cu and of SO_4 liberated against the electrodes in the same time is four of each: hence the anode region of the cell loses only one SO_4, while the cathode region loses three Cu.

The reasoning may be made to look more general.

Consider a compound, AC, arranged in two vessels with a joining tube; let A be anion and C be cation, and let A travel n times as fast as C, so that through the tube we have n equivalents of A passing for every equivalent of C.

By the time one equivalent of each ion has been liberated against the electrode, the ions transmitted by the tube will be x and nx equivalents respectively: hence the anode vessel will have lost altogether $1 - nx$ equivalents of each ion, and the cathode vessel will have lost $1 - x$ equivalents.

But x and nx together convey the whole current, so $x + nx = 1$.

Thus, then, we have as the respective losses of the liberated elements by the two vessels:

$$\text{Loss in anode vessel . . } = 1 - \frac{n}{1+n} = \frac{1}{1+n};$$

$$\text{Loss in cathode vessel . } = 1 - \frac{1}{1+n} = \frac{n}{1+n};$$

Hittorf's well-known expressions.

Or consider it this way:

By the time one equivalent of copper has been deposited, and one of SO_4 has attacked either the anode itself if of copper, or the water in its neighbourhood if of platinum, forming $CuSO_4$ in the one case, H_2SO_4 in the other—no matter which:—by the time all this has happened, $3x$ atoms of SO_4 have passed from neighbourhood of cathode towards anode, and x of copper have gone the other way.

The cathode liquid has thus lost $1 - x$ of copper, and so must have lost $1 - x$ of SO_4 too, no more and no less, or else it would contain isolated radicles.

The anode liquid has gained these $1 - x$ atoms of SO_4; and they may be also reckoned as $3x$, as we just now saw; wherefore $x = \frac{1}{4}$. The cell happens not to lose any SO_4 by deposition, but, instead, it either loses an equivalent of O or gains an equivalent of Cu, according to the nature of the anode.

So the final result in any case is a transfer of $\frac{3}{4}$ equivalent of SO_4 from cathode vessel to anode vessel, combined with a transfer of $\frac{1}{4}$ equivalent of Cu in the opposite direction: a net loss of $\frac{3}{4}$ equivalent of copper sulphate by the cathode solution: and, in the anode liquid, either a net gain of $\frac{3}{4}$ equivalent of $CuSO_4$, if the anode be copper; or a gain of a whole equivalent of H_2SO_4 combined with a loss of $\frac{1}{4}$ equivalent of $CuSO_4$ and of a whole equivalent of oxygen, if the anode be platinum.

All this is in fair agreement with experiment. The only obviously weak place is that relating to the production of free acid. According to the above it ought to appear, if at all, only at anode; now in practice, if the experiment be tried, it will be found to appear at cathode too. Still, the local concentration changes are satisfactorily and very simply explained by this customary migration hypothesis.

But before we decide that the sufficiency of this explanation proves its necessity or actual truth, let us try whether we cannot get the same result on another, and not only plausible but really quite necessary, hypothesis, viz. the hypothesis that the solvent conducts some of the current as well as the salt dissolved; and let us see whether this alone will not account for the whole 'migration' phenomenon, even though opposite corresponding ions be supposed to travel at equal rates.

By drawing a scheme, say, for the electrolysis of $CuSO_4$ solution with platinum electrodes, we can soon see that this hypothesis will do what is wanted; for we find, that if $CuSO_4$ conducts the whole current, the

decomposed equivalent comes half from each half of the cell—the anode half and the cathode half; whereas, by supposing H_2O to conduct the whole current, $CuSO_4$ is decomposed by secondary action only in the neighbourhood of the cathode, and the amount of salt in the anode portion of the solution remains unchanged. The proper apportioning of conduction, therefore, explains migration just as well as the direct Hittorfian hypothesis.

Moreover, we shall find that this mode of regarding the subject is capable of explaining the formation of free acid or other secondary products exactly where experiment shows them to be formed. If it be found to account for their appearance in precisely right amount, it may be held to be proved; let us therefore examine more closely the full effect of supposing the current to be shared between the two ingredients of a doubly compound liquid in any assigned proportion.

Theory of Double Electrolysis: or the decomposition of a mixture of two substances.

We must begin by excluding the possibility of double decomposition or interchange of radicles, because if such occur there are really not two substances mixed, but four. No stress is to be laid on the word 'mixture,' as distinct from combination; and I shall consider a solution of copper sulphate as a mixture of $CuSO_4$ and H_2O, dilute acid as a mixture of acid and water, without troubling about the perfectly certain fact that all these cases (and probably most other cases) of mixture are really cases of—it may be very feeble—chemical combination. But commonly called 'mixed' solutions, such as the heading might at first sight suggest—like, say, $KI+NaCl$, or even $KI+KCl$—are excluded, not only by double decomposition, but by the presence of water, which is distinctly a *third* substance.

Limiting ourselves strictly then to two substances, *e.g.*, a salt and water, there are still several possible cases:

(1) The liberated ions may belong wholly to one of the two compounds.
(2) The liberated ions may belong one to each of the two compounds.
(3) They may each belong to both.

At first sight the first case is a mere simple decomposition, like that of a fused salt, but not necessarily so; it all depends upon whether the substance is *primarily* decomposed or not—*i.e.* on whether it conducts the whole current or not. If the other substance, whose ions are not liberated, either wholly or partially conducts the current, it is a true case of double electrolysis.

To simplify the problem we will use unalterable electrodes—*e.g.* platinum; and we will suppose that the liberated ions do not dissolve, or at any rate *have not* dissolved, in the liquid, else the mixture will not remain merely dual but will become more complex.

We have next to make some hypothesis concerning the relative speeds of opposite corresponding ions—*i.e.*, of the anion and cation of one and the same substance. For the sake of simplicity I will first make the simplest assumption, in favour of which several considerations may be urged, though none of them are conclusive—viz. that opposite corresponding ions travel at equal opposite rates. We shall find this sufficient to

explain every migration phenomenon, and we can see the effect of generalising it afterwards.

Consider, now, the mixture $AC + A'C'$, where A and A' stand for anions, C and C' for cations.

Let the current be conducted by these two compounds in the ratio λ to λ', so that $\lambda + \lambda' = 1$; and, in order to isolate the portion of the liquid near either electrode and study the changes therein occurring, we may picture the whole fluid as contained in two vessels united by a siphon tube; and we shall call the two vessels the anode vessel and the cathode vessel, respectively.

Further, we may if we like think of AC as sulphate of copper, and of $A'C'$ as water; the products of deposition, or liberated ions, will then be C and A' respectively, and the bye-product AC' will be free sulphuric acid. This example therefore belongs to case (2) above, one ion belonging to each compound; and this will serve well enough as an example to work out.

Picturing the convection of electricity by the ions through the tube, we see that A carries a quantity of negative electricity $\frac{1}{2}\lambda$, A' a quantity $\frac{1}{2}\lambda'$; C carries $\frac{1}{2}\lambda$ of positive electricity, and C' a quantity $\frac{1}{2}\lambda'$. So by the time a unit quantity of electricity has been conveyed, and an equivalent of anion and cation deposited on anode and cathode respectively, the following changes have occurred in the ingredients of the fluid in the two vessels. The cathode vessel has gained $\frac{1}{2}\lambda$ equivalent of C from the anode vessel, but it has lost a whole equivalent by deposition, so its net loss of C, which we may write dC, is $1-\frac{1}{2}\lambda$. Of the other cation it has lost none, and has gained $\frac{1}{2}\lambda'$ from the other vessel, so we may write $dC' = -\frac{1}{2}\lambda'$. Of anodes it has lost some of both, but only by travelling to the other vessel, and accordingly $dA = \frac{1}{2}\lambda$, and $dA' = \frac{1}{2}\lambda'$. Similar reasoning easily applies to the anode vessel.

Then passing from the elements only to consider the compounds, we recognise at once that a compound is lost by the loss of *either* of its elements, and that those elements may be either lost absolutely or may be found in new combinations. We thus soon perceive that the loss of the compound AC in the cathode vessel is equal to its loss of C, *i.e.* to its major loss; that is, $d(AC) = dC = 1-\frac{1}{2}\lambda$. The loss of $A'C'$ in this same vessel is equal to whichever is the bigger of the two losses, dA' or dC'; and as dC' is, in the present instance, not a loss, but a gain, there is no doubt but that $d(A'C') = dA' = \frac{1}{2}\lambda'$.

Similarly with the other vessel.

But there remains to be considered what becomes of the unpartnered balance of all the various elements, for unless dC equals dA in both vessels, there will be in one or other an excess of either A or C—in the present case of A; and, again, unless dC' equals dA' there will be an excess again—in this case of C'; hence we have the new compound AC' formed:—in amount, $d(AC') = dA - dC = dC' - dA'$.

The equality of $dA - dC$ and $dC' - dA'$ is necessary, unless it is possible to obtain isolated ions; and it will be found that they come out equal from the preceding values, and that $d(AC') = -\lambda'$ in the cathode vessel, while in the anode vessel $d(AC') = -\lambda$.

Represent all this now in a table :—

Result of Double Electrolysis on the liquid in anode and cathode vessels, by the time one equivalent of an ion belonging to each substance has been deposited.

Substance	Loss in cathode vessel	Loss in anode vessel	Total loss
A	$\frac{1}{2}\lambda$	$-\frac{1}{2}\lambda$	0
A′	$\frac{1}{2}\lambda'$	$1-\frac{1}{2}\lambda'$	1
C	$1-\frac{1}{2}\lambda$	$\frac{1}{2}\lambda$	1
C′	$-\frac{1}{2}\lambda'$	$\frac{1}{2}\lambda'$	0
AC	$1-\frac{1}{2}\lambda$	$\frac{1}{2}\lambda$	1
A′C′	$\frac{1}{2}\lambda'$	$1-\frac{1}{2}\lambda'$	1
AC′	$-\lambda'$	$-\lambda$	-1

The facts of migration are thus perfectly accounted for, and a good deal beside. Thus free acid is shown to appear both at anode and cathode in the electrolysis of sulphate of copper with platinum electrodes: the amount at anode being $\frac{\lambda}{\lambda'}$ of that at cathode. Hence a determination of the relative amount of free acid in anode and cathode vessels at once gives a means of determining $\lambda : \lambda'$, the proportion in which the current is shared by the two substances, if the above hypothesis be true.

It is easy enough to put Hittorf's migration number n into the above table instead of λ: one has only to write $\frac{1}{2}\lambda = \frac{1}{n+1}$; but only three lines of the table have any meaning on the Hittorfian hypothesis—viz. the first, third, and fifth lines—relating to the loss of the compound AC in the respective vessels; the solvent, or other compound, A′C′, is ignored, and the production of free acid near cathode is not supposed to occur. But it *does* occur, as some preliminary experiments I have made prove.

Our hypothesis makes the formation of acid and everything else independent of intensity of current. Experiment may not confirm this; but then we must remember that we have assumed no *mixture of ions* to be liberated, and it is known that with intense currents some hydrogen is given off at cathode as well as copper deposited. If this be taken into account the reasoning must, of course, be generalised.

A more formidable objection, however, may be made to the theory, viz. that it virtually assumes the conduction by the two sets of atoms to be independent; for instance, the λ portion of current starting fairly away from the neighbourhood of electrodes *via* $CuSO_4$ is supposed to go through $CuSO_4$ all the way, and not to come across patches of water or to take either ingredient of the liquid at random.

Consider for a moment what would happen if this did occur. Take a chain, $CuSO_4$, $CuSO_4$, H_2O, H_2O, H_2O, H_2O, $CuSO_4$, $CuSO_4$, H_2O. Imagine the usual Grotthus action to go on through the chain: the result is $2H_2SO_4$ and $1CuO$. This is an unstable condition, or condition of non-minimum energy; so one H_2SO_4 will combine with the CuO; but it need not combine at once, because there is no need for the two compounds to be formed close together. Hence we must expect free acid sometimes to make its appearance *in the middle of the liquid away from either electrode*, and also for CuO to appear (in the form of some basic salt I suppose) too. Choosing proper materials, an action of this kind might be readily looked for, but I have never heard of its being detected,

and it is so unlike what we know of the behaviour of electrolytes in general that until proof to the contrary is forthcoming I feel compelled to believe that a current fairly starting in AC continues in it all the way, that a current starting in A′C′ likewise continues in that, and that secondary actions, or passage of current from AC to A′C′, only occur in the immediate neighbourhood of the electrodes.[1]

It is easy to illustrate the preceding table of the changes in the solutions by a diagram of a special case :—

Scheme of decomposition of sulphate of copper solution with platinum electrodes on the gratuitous assumption that water conducts $\frac{1}{4}$ the whole current.

Cathode			Anode
←$CuSO_4$	$CuSO_4$	. . . . $CuSO_4$	$CuSO_4$
H_2O	H_2O	H_2O	H_2O ↗
←$CuSO_4$	$CuSO_4$	$CuSO_4$	$CuSO^4$
H_2O	H_2O	. . . . H_2O	H_2O ↗
←$CuSO_4$	$CuSO_4$	. . . . $CuSO_4$	$CuSO_4$
H_2O	H_2O	H_2O	H_2O ↗
←$CuSO_4$	$CuSO_4$	. . . . $CuSO_4$	$CuSO_4$
H_2O	H_2O	H_2O	H_2O ↗

The arrangement of the symbols indicates the constitution before passing the current: the dotted lines and arrows indicate the state of affairs after four units of electricity have passed, on the arbitrary assumption (only made for the sake of illustration) that the $CuSO_4$ conducts three times as much current as the water does, *i.e.* that $\lambda = \frac{3}{4}$ and $\lambda' = \frac{1}{4}$. Inserting these values in the previous table, and multiplying by four, to represent that four units of electricity have passed, it becomes :—

Substance	Loss in cathode vessel	Loss in anode vessel	Total loss
SO_4	$1\frac{1}{2}$	$-1\frac{1}{2}$	0
O	$\frac{1}{2}$	$3\frac{1}{2}$	4
Cu	$2\frac{1}{2}$	$1\frac{1}{2}$	4
H_2	$-\frac{1}{2}$	$\frac{1}{2}$	0
$CuSO_4$	$2\frac{1}{2}$	$1\frac{1}{2}$	4
H_2O	$\frac{1}{2}$	$3\frac{1}{2}$	4
H_2SO_4	-1	-3	-4

[1] It is assumed, in the text, that the ingredients of the liquid are thoroughly mixed. If they are purposely arranged in layers, free acid or free base may certainly make its appearance at the bounding surfaces. In fact, Faraday has observed the phenomenon, Exp. R. § 494 ; for he passed a current from strong $MgSO_4$ solution into 'water' (*i.e.*, really weak $MgSO_4$ sol.) and found a deposit of magnesic hydrate at the layer of demarcation. It is interesting to note that in January 1886 Kohlrausch accepts this experiment as proving that water does in some cases share in the conduction, though he still considers its share as negligible in all but exceedingly weak solutions.

And all this is exactly borne out by the above scheme: for one notes that 3 atoms of acid make their appearance in the anode vessel and 1 atom in the cathode vessel; that $\frac{1}{2}$ an atom of O is transferred one way, and $\frac{1}{2}$ an atom of H_2 the other way; that $\frac{3}{2}$ atoms of Cu travel from anode vessel to cathode vessel, but that 4 are deposited, making the net loss in this vessel $4 - 1\frac{1}{2} = 2\frac{1}{2}$; and so on.

Modification of the above table by the introduction of Kohlrausch's hypothesis that each ion has its own rate of travel.

Consider now what will happen if, instead of assuming that opposite corresponding ions must go at the same pace, we assume that each has its own pace; and that the sharing of the current between the ingredients of the fluid depends on these intrinsic ionic velocities and on the proportion of each substance present.

Of the two compounds AC and A′C′, we must affix a mass-velocity to each ion—say, α, γ, α', γ', respectively; so that

$$\alpha + \gamma \text{ is what we formerly called } \lambda,$$

and $\quad \alpha' + \gamma' \quad$ " $\quad$ " $\quad \lambda'$,

but no longer does $\alpha = \frac{1}{2}\lambda$. So the above table becomes:—

Results of Double Electrolysis, &c.

Substance	Loss in cathode vessel	Loss in anode vessel	Total loss
A	α	$-\alpha$	0
A′	α'	$1-\alpha$	1
C	$1-\gamma$	γ	1
C′	$-\gamma$	γ'	0
AC	$1-\gamma$	γ	1
A′C′	α'	$1-\alpha'$	1
AC′	$-(\alpha'+\gamma')$	$-(\alpha+\gamma)$	-1

This gives the relative formation of free acid in the two vessels exactly the same as before—viz. $\dfrac{\alpha+\gamma}{\alpha'+\gamma'} = \dfrac{\lambda}{\lambda'}$.

It is a trifle more general than the former hypothesis, in the non-equality of α and γ, and of α' and γ', and this fact may furnish a method of distinguishing between the two hypotheses.

From the table we see a way to find these values, thus:

$$\gamma = \text{loss of AC in the anode vessel},$$
$$\alpha' = \text{loss of A}'\text{C}' \text{ in the cathode vessel},$$
$$\alpha + \gamma = \text{gain of AC}' \text{ in the anode vessel},$$

and $\quad \alpha + \gamma + \alpha' + \gamma' \equiv 1.$

In Kohlrausch's theory, indeed, ionic velocities are supposed to be pretty well known, and accordingly we may seek to compare the relative quantity of free acid, found in the two vessels, with the ratio $\dfrac{\alpha+\gamma}{\alpha'+\gamma'}$. But then Kohlrausch's velocity-numbers are founded on a strictly Hittorfian view of migration, and do not depend on the assumed conductivity of all the ingredients present in a fluid: they are intended to stand for

the actual speed of moving salt atoms and the water atoms are neglected. Kohlrausch's numbers are in fact totally different things from our α, γ, α', γ', which include along with the idea of velocity the idea of amount of substance available for conducting the current. In terms of a notation to be used later, $\frac{\alpha + \gamma}{\alpha' + \gamma'} = \frac{N_1 u_1}{N_2 u_2}$.

Generalisation of the above, to suit the case when a mixture of ions may be given off at each electrode.

If we now extend our view a little to cover cases (1), (2), and (3) at the same time—that is, to take account of a possible *mixture* of liberated ions, such as one frequently gets with intense currents, and may get at any time, we must write the actual amount of liberated cations c and c', and of anions a and a', where, of course, $c + c' = a + a' = 1$; and the table becomes the following:—

Results of Double Electrolysis, &c.

Substance	Amount of substance lost by cathode vessel	Amount of substance lost by anode vessel	Total loss
A	α	$a - \alpha$	a
A′	α'	$a' - \alpha'$	a'
C	$c - \gamma$	γ	c
C′	$c' - \gamma'$	γ'	c'
AC	$(c - \gamma)$ or (α)	(γ) or $(a - \alpha)$	(c) or (a)
A′C′	(α') or $(c' - \gamma')$	$(a' - \alpha')$ or (γ')	(a') or (c')
AC′	$(\alpha + \gamma) - c$	$a - (\alpha + \gamma)$	$(a - c)$
A′C	or $c - (\alpha + \gamma)$	or $(\alpha + \gamma) - a$	or $(c - a)$

This table looks more complex than the others because it contains alternatives; they are not ambiguities, and it is easy enough to know in any particular case which is the right alternative, but it cannot be expressed by the general symbols, because it is impossible to know whether $c - \gamma$ or α is going to be the bigger. The rule is that the bigger of the two alternatives about the loss of AC and A′C′ is the true one; and the substance formed will be at the same time decided by the values which in the last two alternative lines come out negative.

Or take it conversely. Suppose A′C is the substance formed in both vessels as the bye-product, then the second set of alternatives are the right ones all through; but if AC′ is the substance formed in both vessels, the first set of alternatives are correct; while, if it should happen that AC′ is formed in the anode vessel and A′C in the cathode, then the first set of alternatives are true for the anode vessel and the second set for the cathode vessel.

With actual chemical substances it is usually easy to see whether the bye-product will be AC′ or A′C, and thus to fix the alternatives. Thus with a solution of copper sulphate, it is plain that the bye-product will be H_2SO_4 in both vessels, and not CuO.[1]

As an illustration of the possibility just mentioned, about the bye-products being different in the two vessels, consider the electrolysis of a

[1] Remember that the electrodes are supposed to be platinum, so that oxygen is liberated; with a *copper* anode it is easy enough to form CuO, as has already been said.

salt of some metal more electropositive than hydrogen—for instance, Glauber's salts. Neither Na nor SO_4 can be liberated—the liberated ions must be H and O; but the water is not merely primarily decomposed, Na_2SO_4 shares in the conduction of the current, and accordingly secondary actions go on, forming acid at anode and alkali at cathode, as is perfectly well known. The last table gives every detail of the action, and points out that in order to determine experimentally how much of the current is conveyed by the salt and how much by the water we have only to measure either the amount of acid or the amount of alkali produced. For in this case $a' = c' = 1$; $a = c = 0$; the production of acid is $\alpha + \gamma = \lambda$, the proportion of current conveyed by the salt; and the production of alkali is precisely equivalent.

General Theory of Multiple Electrolysis.

It is now only a matter of writing to make a table for the most general case of electrolysis of a single liquid containing any number of substances. It is not much use now excluding double decomposition, and we will begin by letting the liberated ions be the most complicated mixture possible.

Mix together the substances $A_1C_1 + A_2C_2 + \ldots + A_nC_n$; the result of the mixing is that each anion is liable to be combined with all the cations, forming $A_1C_1 + A_1C_2 + \ldots$, and so on for the others; say $A_1\Sigma C + A_2\Sigma C + \ldots$; or altogether $\Sigma A.\Sigma C$.

Let the liberated ions be $a_1, a_2, \ldots a_n$, equivalents of $A_1, A_2, \ldots$ &c. and $c_1, c_2, \ldots c_n$, equivalents of $C_1, C_2, \ldots$, &c. respectively.

Let the mass-velocities of the independent ions be

$$\alpha_1, \alpha_2, \ldots \alpha_n \text{ for the anions,}$$

and

$$\gamma_1, \gamma_2, \ldots \gamma_n \text{ for the cations.}$$

Then the following equations hold among the quantities:—

$$\Sigma a = \Sigma c = 1,$$
$$\Sigma \alpha + \Sigma \gamma = 1;$$

and, if it is worth while attempting to specify how much of the current each substance conveys,

$$\alpha_1 + \gamma_1 = \lambda_1; \quad \alpha_2 + \gamma_2 = \lambda_2; \ldots, \text{\&c.}$$

[Further, if my notion is true that an electric current necessarily consists of equal positive and negative currents, $\Sigma\alpha = \Sigma\gamma$. I even venture to think it *probable* that $\alpha_1 = \gamma_1$, $\alpha_2 = \gamma_2$, &c. See below.]

Now the portion of above table referring to the loss of elements is simple enough:—

Element	Amount lost in cathode vessel	Amount lost in anode vessel
A_1	α_1	$a_1 - \alpha_1$
A_2	α_2	$a_2 - \alpha_2$
$\vdots$	$\vdots$	$\vdots$
C_1	$c_1 - \gamma_1$	γ_1
C_2	$c_2 - \gamma_2$	γ_2
$\vdots$	$\vdots$	$\vdots$

But when you come to the compounds there is no definiteness; by reason

of the double decomposition which has gone on. Moreover, there are the apparent alternatives, just as in the last table. To get rid of alternatives, decide that the liberated ions are single, one anion A_k, and one cation C_l, where k and l may be equal as a special case. Then the portion of the table referring to loss of compounds is :—

Original substance	Lost in cathode vessel	Lost in anode vessel	Total loss
$A_1(\Sigma C - C_l)$	α_1	$-\alpha_1$	0
$A_2(\Sigma C - C_l)$	α_2	$-\alpha_2$	0
$\vdots$	$\vdots$	$\vdots$	$\vdots$
$A_k(\Sigma C - C_l)$	α_k	$1-\alpha_k$	1
$\vdots$	$\vdots$	$\vdots$	$\vdots$
$A_n(\Sigma C - C_l)$	α_n	$-\alpha_n$	0
$C_l(\Sigma A - A_k)$	$1-\gamma_l$	γ_l	1

If no double decomposition had gone on, the substances would have simply been A_1C_1, A_2C_2, &c. The meaning of $A_1(\Sigma C - C_l)$ is: all the compounds into which A_1 happens to enter, with the express exclusion of A_1C_l, this being considered separately, along with A_2C_l, A_3C_l, . . ., &c., in the last line of the table.

The remainder of the table, dealing with the secondary or bye-products formed, is too indeterminate to be instructive; for even if double decomposition had been excluded originally, it must be supposed to occur now, and the substances formed can only be written :—

Substance formed in cathode vessel	Amount	Substance formed in anode vessel	Amount
$A_1(\Sigma C - C_1 - C_l)$	$\alpha_1 + \gamma_1$	$C_1(\Sigma A - A_1 - A_k)$	$\alpha_1 + \gamma_1$
$A_2(\Sigma C - C_2 - C_l)$	$\alpha_2 + \gamma_2$	$C_2(\Sigma A - A_2 - A_k)$	$\alpha_2 + \gamma_2$
. . . .	. . .	. . . .	. . .
$A_l(\Sigma C - C_l)$	$1-(\alpha_l + \gamma_l)$	$C_k(\Sigma A - A_k$	$1-(\alpha_k + \gamma_k)$
. . . .	. . .	. . . .	. . .
$A_n(\Sigma C - C_n)$	$\alpha_n + \gamma_n$	$C_n(\Sigma A - A_n - A_k)$	$\alpha_n + \gamma^n$

where $A_1(\Sigma C - C_1 - C_3)$ stands for $A_1C_2 + A_1C_4 + A_1C_5 + \ldots$, or any of them—*i.e.* for all the possible new combinations of A_1 with cations; the C_1 being excluded because A_1C_1 is certainly not a new compound; and C_l being excluded because, being the cation deposited on the electrode, there is bound to be a deficiency of it rather than an excess, unless indeed more is brought over by migration than is deposited.

Cases of even this anomaly were discovered by Hittorf among the iodides and chlorides of zinc and cadmium, especially when dissolved in alcohol; more than one equivalent of iodine is carried over towards anode, as much indeed, in one case, as two equivalents. This, however, is regarded as exceptional by everybody, and is usually explained by supposing a sub-salt to travel bodily with the simple ion thus: $3CdI_2 = Cd + (2CdI + 2I_2)$, where the quantity in brackets may be the true anion. The same idea has been extended to other and more ordinary cases.

Objections to the idea of unequal velocities of anions and cations.

The bare notion of unequal molecular velocity has received considerable and important development at the hands of Quincke, Wiedemann, and Kohlrausch; but they all accept the fact, and suggest modes of accounting for it. We will therefore defer consideration of their theories to a later head. What I wish to point out is that migration data afford no *proof* that ions travel at unequal rates, because the facts can be accounted for without any such assumption, as has been shown at length; but if I have to state what objection I feel towards considering the anion and cation velocity unequal, I can only answer in an unsatisfactory manner as follows:—

1st. Electricity is known to obey the laws of an incompressible fluid; and whether for positive electricity or for negative electricity, this is equally true. It may well be that electricity is far from being such a fluid, or pair of fluids, but there must be some analogy or they would not obey so exactly the same equations. If one allows mental images of electric actions, the guise of an incompressible, indestructible, uncreatable fluid, always flowing in closed circuits, naturally suggests itself for either kind of electricity. Equal quantities of opposite kinds in coincidence do indeed neutralise all electrostatic effect, but one does not conceive of their annihilating each other.

2nd. In certain cases an electric current is *known* to consist of equal opposite streams of positive and negative electricity. In a simple binary (fused) electrolyte this is so (see above); and in the convection portion of the circuit of a Holtz machine it is so.

If provisionally these lemmas be granted, the argument is obvious.

Include one or other such arrangement for insuring equal opposite flow in any circuit, along with many kinds of voltameters. Can one think of unequal rates of flow of opposite electricities in one part of a circuit and equal rates of flow in another? Not unless it is possible for equal streams of opposite electricities to meet and annihilate each other. And if we can thus control and make equal the electric streams without affecting phenomena in the slightest, must they not always be equal?

And it is plain that equality of the electric streams renders necessary the equal speed of anion and cation, since by Faraday's laws atomic charge is constant. Not, indeed, that this rigidly requires that *each* anion should travel at the same rate as its corresponding cation, or that $\alpha_1 = \gamma_1$, $\alpha_2 = \gamma_2$, &c. All is satisfied if the anions *as a whole* travel as quick as the cations as a whole—*i.e.* if $\Sigma\alpha = \Sigma\gamma$; but it is difficult to think of the relation as being always satisfied unless each individual α equals each individual γ: the same kind of argument as that which leads one to 'equate coefficients.' But less rigorous! Granted. I do not pretend that any of this is a rigorous argument; it is little better than a statement of prejudice with an attempt at justification.

To see if any definite and unambiguous experimental answer can be obtained to the question, 'At what rate do ions travel?' I propose to try a modification of those old experiments with electrolytes in series, where a precipitate is formed in the middle one of three vessels. For instance, use $BaCl_2$ in the anode vessel, Na_2SO_4 in the cathode vessel, and in the intermediate vessel, which is to be in the form of a long tube, dilute HCl. Then pass a current, and observe whereabouts, how soon, and with what appearances, the precipitate shows itself.

Innumerable similar experiments suggest themselves, but it is needless to specify any more of them at present.

III. Quantitative Laws of Electrolysis.

The main laws known at the present time concerning the passage of electricity through liquids may be denominated, (*a*) Ohm's or Kohlrausch's, (*b*) Faraday's two laws, (*c*) Joule's, or Helmholtz's, or Thomson's law.

(*a*) *Ohm's Law of Electrolytic Conduction.*

The researches of Kohlrausch and Nippoldt, and several others, give us very good grounds for asserting that, in all ordinary cases of electrolytic conduction, Ohm's law is at least approximately obeyed: currents being proportional to E.M.F. actually applied to the liquid. It is exceedingly important to test this law in liquids with the utmost accuracy, as has been done for metals by a British Association Committee (Maxwell and Chrystal), but the research would be a very difficult one. We have seen reason for guessing that with violent currents the law may perhaps begin to fail, even if it be exact for weak currents; but on Maxwell's theory of light it can hardly be quite exact for any current, because the optical transparency of electrolytes shows that they behave as dielectrics to very rapidly alternating E.M.F.s. But the law is very nearly true any way, and this fact of itself is important, as showing that infinitesimal E.M.F.s can produce a current.

Now if there were any chemical cling between the atoms taking part in conduction this could not be—a finite E.M.F. would be needed to tear them asunder; and this is what physicists mean by using the term 'dissociation' in this connection. The atoms are so free of one another that they must be either really or virtually dissociated. Not all the molecules of the compound need be in this condition, of course, only a certain percentage of them, and the conductivity of the liquid must depend upon the value of this percentage. It may be supposed nil in a perfectly pure homogeneous liquid like H_2O; it may be supposed to be caused by the presence of foreign molecules (*e.g.* of salt or acid); and it may be supposed to increase with rise of temperature.

The transparency of an electrolyte may, however, be explained without assuming any violation of Ohm's law, by supposing that the percentage of dissociated atoms is too small to perceptibly affect the properties of the liquid in bulk. On this hypothesis, rise of temperature, or other mode of increasing conductivity, might perhaps cause some increase in opacity; moreover it is to be remembered that the transparency of electrolytes for long waves is possibly very small.

(*b*) *Faraday's Two Laws.*

(1) The voltametric law.
(2) The law of electro-chemical equivalence.

Law 1 asserts that the amount of electro-chemical decomposition is a precise measure of the amount of electricity conveyed; *i.e.* that no electrolyte for which the law is true possesses a trace of metallic conductivity; or, that electrolytic conduction and chemical decomposition are precisely correlative.

The law has been most exactly verified for nitrate of silver solution

by Lord Rayleigh; for this substance, therefore, we know that it is true to a high degree of accuracy. For other substances our knowledge is at present only approximate, the main difficulty in its verification lying in the prevalence of secondary actions and the confusion they cause. So great is the influence of these actions that in some cases an electrolyte has been asserted to conduct only metallically, and not to be decomposed at all. This has been said, for instance, of the fused iodide and chloride of mercury. A strong current may be sent through these fused salts with carbon electrodes and no products of decomposition shall appear, because they dissolve and diffuse through the liquid with such surprising velocity. J. W. Clark [1] has proved this to be the explanation, and has succeeded in getting off a good supply of mercury, and of iodine or chlorine, by separating the electrodes by a sufficiency of intervening porous material, which, whether it retard true diffusion or not, certainly hinders convection.

But of course such an experiment has no exact quantitative signification until every trace of recomposition is avoided, and the theoretical amount of free ions obtained. And this is just the difficulty; for even in simple acid water, if any air be dissolved in the water it is well known that an insufficient supply of hydrogen comes off, while if the water is *not* saturated with oxygen, the supply of oxygen must be deficient by reason of solution.

If oxygen be estimated by *volume* it will be apparently deficient for another reason; but the better way of estimating it is by loss of weight, which gets over the ozone difficulty.

Helmholtz has taught us how to get over the dissolved air difficulty, by making a most ingenious air-free cell, described in the Faraday Lecture, 1881; and he shows that in such a cell polarisation is produced by infinitesimal currents, and no permanent leak goes on through the cell until the applied E.M.F. attains a certain value. This is a perfectly valid proof that no trace of metallic conduction exists in air-free acid-water, and that accordingly for this substance Faraday's law 1 is true.

We have already expressed the law in several forms of words. Helmholtz expresses it as follows: 'Through each section of an electrolytic conductor we have always equivalent electrical and chemical motion.' And if this fact of equivalent electrical and chemical motion be expressed, as Ampère very naturally expressed it, by calling it a convection of electricity by the moving atoms of matter, we may state Faraday's law 1 thus:

Electrolysis is a kind of electrical convection rather than conduction, each atom carrying a charge with it; and the charge conveyed by every atom of a given substance is the same.

Obviously a vitally important statement if the slight amount of hypothesis involved in it is legitimate, as I fully believe it to be; and it is the one virtually adopted by Clerk Maxwell in his treatise.

Law 2 asserts that when a current is sent through a series of different substances, the mass of each substance liberated (or decomposed, or dissolved, or whatever it is that happens to it) is proportional to its ordinary chemical equivalence: or, that the amount of any substance acted upon during the passage of a given quantity of electricity is equal to its molecular weight divided by its atomicity, or, more explicitly, its molecular weight divided by the number of bonds which under the particular

[1] *Phil. Mag.*, November 1885.

circumstances happen to be loosed or joined, per molecule of that substance, be it element or be it compound.

Evidence for the truth of this law has been accumulated by Daniell and Miller, by Wiedemann, Hittorf, Matteucci, Becquerel, Soret, and Buff. They all separate the anode from the cathode vessel by various devices, and it appears as if the more carefully secondary actions are prevented or allowed for, the more nearly is the law true. It may be sufficient to refer to Wiedemann's 'Elektricität' for an account of a mass of research.

Further evidence may be suggested as given by the behaviour of certain electrolytes in series-contact, without electrodes intervening, after the manner of Davy; for, if two meeting ions were not precisely equivalent, the one in excess would have to appear in a solitary state. Such a phenomenon might be well looked for, but it has never yet been certainly observed.

The physical import of law 2 is that it extends the statement of law 1, about each atom in a single substance having the same definite electric charge, to all electrolytes, and enables us to conclude that a definite quantity of electricity belongs to each unit of affinity of every atom of whatever kind; in other words, that every monad atom or radicle (while being liberated on an electrode, at any rate) has associated with it a certain definite quantity of electricity, no matter from what compound it is being liberated, and no matter what the name of the radicle itself may be; that every dyad radicle has twice this quantity associated with it, every triad three times as much, and so on.

It is impossible to overlook the immense interest of such statements as these to any chemist wishing to grasp the real meaning of chemical combination and affinity. But the tremendous import of the law to physicists also may be more vividly indicated by pointing out that the electric charge of a nascent monad atom is a kind of natural unit of electric quantity, *and that fractional portions of such units are*, in electrolysis at least, *unknown*. One may have integral multiples of this natural unit, as in dyads and triads, but one cannot have submultiples, until chemists discover some quantivalence less than that of hydrogen, or rather until they see reason to abandon the idea that quantivalence proceeds by integers (the basis of their 'atomic theory') altogether.

Maxwell no doubt intends to call attention to the superlative interest of the fact that there appears to be a non-divisible electrical unit, when he calls it 'a molecule (his customary cautious name, intended to include atoms also if they exist) of electricity.' And Helmholtz does not shrink from staring the possibility in the face that electricity may turn out to be as 'atomic' as matter.

Atomic Idea of Electricity; Electrostatic Theory of Chemistry.

Let us first consider what is really the evidence for such a view. Electricity is found to associate itself with the atoms of matter in multiples of one fundamental quantity, but never in fractions of it; it does not then follow that fractions of this quantity are impossible, but it may well be that we have never yet dealt with them. The evidence for the atomic nature of electricity is pretty much of the same nature as that for the atomic nature of matter. Gains and losses of electricity are apparently continuous, but so they are of matter; all that is necessary to satisfy

experience is for the atom of electricity to be smaller than any quantity hitherto measured.

Whether the charge of a monad atom be indivisible or not, it is certainly a natural unit of electricity, and it becomes of great interest to calculate its value. This is easily possible to the same degree of approximation, as we know the size of an atom. The electrical charges in the atoms of a gramme of water are known accurately enough, from ordinary electro-chemical-equivalent determinations, viz. $1{\cdot}5 \times 10^{13}$ electrostatic units of each kind; the number of molecules in a gramme of water may be considered as something between 10^{24} and 10^{25}; and accordingly the charge of a monad atom is something like 10^{-11} or 10^{-12} electrostatic units.

Now this is very small, less than the hundred trillionth of a coulomb, and if it were really an ultimate atom of electricity, it is wholly unlikely that the fact would have been noticed. It is possible, however, to think of some phenomena which may afford an indication one way or the other, and I shall venture to suggest one or two later.

The charge of an atom is so small that its potential cannot turn out high, on any customary hypothesis as to actual atomic magnitude, provided ordinary considerations of electrostatics apply to atoms. It is difficult to know whether they apply or not until it can be shown that absolute vacuum has a specific inductive capacity. The transparency of interstellar space, and the velocity of radiation in it, would seem respectively to answer the question in the affirmative, and to suggest unity as its value. At any rate, when one has no other mode of tackling atomic charges it would seem reasonable to try the ordinary electrostatic laws on them, and see how they fit and what happens.

Consider therefore the following problem.

A number of equal spheres, each charged with a definite quantity of electricity, are commingled with the same number of similar spheres each charged with the same quantity of opposite electricity, the potentials of the spheres being so low that mutual discharge does not occur even during a collision, or so-called 'contact,' of the spheres, and some law of force being assumed between the spheres irrespective of their charges.

I do not propose to attack the problem thus vaguely suggested, because many persons can do it far more easily and thoroughly than I; but certain facts are patent. The potential of each sphere must be lower in the 'combined' state than in the isolated, and, unless an atom be assumed to be extravagantly small compared with the spaces between them in the liquid state, the potential of each isolated atom is but a few volts.

Facts are known which suggest sizes for the actual substance of the molecules, but, without pressing them, one may assume that whereas in the liquid state the distance of the atoms apart is about 10^{-8}, the radius of each of them is about 10^{-9} or even 10^{-10} centimetres; then, the charge of a monad atom being as aforesaid 10^{-11} or 10^{-12}, it follows that its potential, when isolated, is about 3 volts.

If such an atom pair off with another of opposite sign, the potential of each will fall as they approach; becoming, when the distance between their nearest points is one tenth of the radius of either, about 1·2 volt,[1]

[1] See table by Sir William Thomson in *Electrostatics and Magnetism*, § 142.

and falling asymptotically to zero as the distance between them still further diminishes.[1]

It is true that this fall of potential has not the result of postponing mutual discharge *ad infinitum*, however near atoms may approach; but I feel constrained to believe that no such discharge ever in practice occurs, from the fact (if it be a fact) that the whole of a liquid can be electrolysed away, and from the assumption that any such discharged molecules would be wholly intractable to electrical influence. To explain non-discharge we can fall back on the rather dark fact of the enormous apparent dielectric strength of vacuum, combined with the very low potentials to which atoms are charged.

I have tried an experiment of electrifying two falling clouds of lycopodium oppositely, and allowing them to mix, or, so to speak, combine. The result has not yet been satisfactory, but lycopodium granules are coarse and weighty bodies, and are unwieldy representatives of atoms. To get anything like such a quantity of each kind of electricity into the grains of a cubic millimetre of lycopodium as exists in the atoms of a cubic millimetre of water, the charge, and therefore the potential, of each granule would have to be enormous, something like a billion volts: for I find the diameter of a lycopodium granule about ·004 centimetre. It is easy to see that a given quantity of both kinds of electricity, shared among a given bulk of equal and definitely arranged spheres, will raise the potential of each by an amount proportional to its superficies.

It may be noted, as interestingly showing the enormous charges which, distributed among the atoms of a substance, produce such an insignificant potential, *i.e.*, as illustrating the prodigious electrical capacity of molecular arrangement, that if the opposite electricities were extracted from a milligramme of water, and given to two spheres one mile apart, those two spheres would attract each other with a force of ten tons![2] (Cf. Helmholtz, Faraday Lecture, 1881.)

A more hopeful substance than lycopodium, for constructing an artificial chemical compound with, is fine smoke, say of magnesia, which hovers in air for a long time.

But, as Clark and I have observed, it is sufficient to electrify such

[1] Or one might work the argument conversely, and perhaps more plausibly, so as to obtain an estimate of atomic, as distinct from molecular, dimensions. Thus:—

The total charge shared among the atoms of a gramme of water is perfectly well known, viz., 1073 electro-magnetic units of each kind. The heat produced during the formation of a gramme of liquid water from its gaseous constituents is, according to J. Thomsen, 4333 thermal units. If two bodies, or sets of bodies, each charged with that quantity of electricity (one set positive, the other set negative), approach each other so as to do this amount of work, their difference of potential must diminish, during the approach, by 1·7 volt.

The fall may be from 1·7 to nearly 0, as the dissociation idea of electrolysis would suggest. Or it may be from 3 to 1·3, as the guess at atomic dimensions in the above text implies. Or atomic charge may be a thing acquired during the act of combination, as the hypothesis of zero charge in a molecular aggregate like HH or OO would imply; in which case the necessary fall of potential must be 3·4 volts.

The first of these alternatives gives for the diameter of an oxygen atom

$$5{\cdot}6 \times 10^{15}\, x^3;$$

$^1/x^3$ being the number of molecules in a gramme of water.

[2] If any cause could make the positive atoms in a drop of water group together and face the negative across a vacuum, a furious Leyden-jar, or 'Globe-Lightning,' would be produced.

smoke with only one kind of electricity in order to cause the particles to combine or coagulate together—doubtless because of minute differences of potential between them: the aggregations soon becoming very large and giving the appearance of snow.

I now fancy that this same phenomenon of aggregation may go on among the atoms of a gas when it is electrified, and may account for the formation of ozone near an electric machine, for the formation of ammonia from nitrogen and hydrogen, and such like.

(c) *Joule's or Helmholtz's or Thomson's law of the dependence of decomposition E.M.F. on chemical combination-energy.*

The deduction of this law from the first law of thermodynamics may be exhibited perhaps most clearly and briefly as follows:

(i.) Definition of E.M.F. as—the work done in a circuit per unit of electricity conveyed, or $E = W/Q$.

(ii.) Definition of Electro-chemical Equivalent as—the mass of substance decomposed per unit of electricity conveyed, or $\epsilon = m/Q$.

(iii.) Definition of Thermal Equivalent as—the heat set free during the formation of one gramme of the substance from the two radicles into which it has just been supposed to be decomposed, provided that none of the energy remains in some form other than that of heat, $\theta = H/m$.

(iv.) Statement of the first law of thermodynamics applied to the electrical decomposition of the said substance in the given way, on the assumption that the whole of the work done by a current is expended in decomposing the substance,

$$W = JH.$$

The simple algebraic consequence of these four equations is

$$E = J\epsilon\theta,$$

which is shorthand for the law, and may be read thus:—the E.M.F. needed to decompose a substance into given constituents is calculable by simple energy considerations from purely thermo-chemical data.

If θ'' stand for the heat production per dyad gramme-equivalent of the substance (*e.g.* per 18 grammes of water, 98 grammes of sulphuric acid, or 136 grammes of chloride of zinc), it is easy to see that

$$E = \frac{\theta''}{46{,}000} \text{ volts};$$

for $J = 42 \times 10^6$, $\epsilon = \dfrac{\mu}{9{,}660k}$, $\theta'' = \dfrac{2\mu\theta}{k}$, where μ is the molecular weight of the substance as compared with an atom of hydrogen, and k is the atomicity or number of bonds loosed in the decomposition supposed.

Values of θ'' are tabulated direct by Julius Thomsen for a great variety of substances, and are quoted in Naumann's 'Chemie,' vol. i. and also partly in Watt's 'Dictionary of Chemistry'; hence the obtaining of the volts needed to decompose a substance, by simply dividing θ'' by 46,000, is extremely convenient.

IV. Discussion of the law (c), and questions concerning Polarisation.

The chemical changes which go on in a circuit wholly electrolytic, or in any homogeneous portion of a circuit, are decomposition and identical recomposition, and consume no energy; accordingly no fresh E.M.F. is needed to send a current through a circuit wholly electrolytic or through a homogeneous electrolyte, *when the force is really applied to it* (*i.e.*, not merely applied to electrodes), and Ohm's law is possibly obeyed by electrolytes exactly as by metals.

But at junctions of metals with electrolytes, or of electrolytes with one another,[1] permanent chemical changes may occur, and at such places a finite E.M.F. must be situated: and the resultant of these may be negative, when it is called polarisation, or positive, when the whole arrangement is called a battery.

Total polarisation may be regarded as the sum of two kinds:

(*a*) Temporary polarisation, existing during continuance of current.
(*b*) Residual polarisation, existing afterwards.

Residual polarisation is caused by a more or less permanent alteration of the surface of the electrodes by clinging or combined ions. Under this head comes the whole subject of secondary batteries.

Concerning temporary polarisation less is known.[2] On Helmholtz's theory it is caused by the deposited but unliberated and still charged ions being unwilling to part with their charges. Whenever the ions are able to combine with the electrode or with the liquid, and thus retain their charges, temporary polarisation is very small. It seems undoubtedly due to the same circumstances as cause the extra energy of the nascent condition of a substance; and it varies very much with the particular state of combination, or uncombination, into which the ions enter when set free from their former union.[3]

The above expression, in the form $\Sigma\,(J\epsilon\theta)$ or $\frac{\Sigma\theta''}{46{,}000}$, or $\frac{\Sigma\theta^{(n)}}{23{,}000n}$, may be used to calculate the theoretical E.M.F. of a battery cell formed of specified constituents in which known reactions go on.

Now is the law really true? Is E. really the E.M.F. needed to decompose a given substance? Or is it only a partial statement of a truth?

It may at once be admitted that whatever *direct* thermal effects the

[1] Du Bois Raymond proved polarisation to be possible at liquid-liquid junctions. He also asserts the existence of '*innere Polarisation*' in a uniform liquid, which would be contradictory of what is said above; but what he observed is plainly connected with capillary E.M.F. and endosmose, and in the light of these is natural enough.

[2] The experiments of Bernstein, as well as some by Beetz and Edlund, have shown how quickly it can rise and decay with make and break of current; so it is scarcely a valid proof of its complete non-existence when a galvanometer switched into a circuit is not deflected. At the same time no sharp distinction can be drawn between temporary and permanent polarisation, any more than between temporary and permanent magnetism.

[3] Mr. J. Larmor gave a short communication to the meeting, 'On the molecular theory of galvanic polarisation,' which he has expanded to a most interesting paper, and published in the *Phil. Mag.* for November 1885. He shows that polarisation, whether natural or artificial, must necessarily diminish surface tension, without any question of exact reversibility; and he calculates the distance apart of the constituent molecules in the electrical layers of a voltameter-condenser, whose capacity is becoming incipiently non-constant.

current may produce, being an expenditure of energy in other than chemical directions, must lie outside the range of the above law, inasmuch as they falsify the assumption of (iv,). Irreversible or frictional heat, and likewise reversible or thermoelectric heat, must thus be considered separately. If ever the E.M.F. of a cell or a voltameter is seriously different from the value calculated on chemical ground it is to be examined whether there be not local heatings or coolings in the cell, whereby the total E.M.F. may be either diminished or increased, being really the sum of two E.M.F.s., a chemical one and a physical or thermoelectric one.

But all this being understood and allowed for, as was really done by Thomson in his original paper in 1851, is the law sustained by experiment for cases other than the Daniell cell and a few other simple ones?

For instance, when two substances combine and produce heat, is any of the heat a direct result of their union, or are electric currents the direct primary result and heat a secondary or derived result? If any of the heat be primarily generated then it is to be surmised that this portion of the whole combination energy is electrically inactive, having no effect on either the positive E.M.F. of a battery or the negative E.M.F. of a voltameter. Secondary actions for instance: it has long been a subject of debate whether the solution of zinc oxide in acid, or of zinc sulphate in water, contributed its full quota to the energy of the current and the E.M.F. of a cell, or whether the combination of zinc with oxygen was more intrinsically effective.

Joule showed how to attack the question for substances composing batteries, by immersing the battery in one calorimeter and its outer circuit in another. Whatever heat necessarily and intrinsically appears in the cell itself must be heat primarily and directly generated; but if all the heat of the battery can be made to appear in the outer circuit, by making the resistance of this circuit high enough, it is proof positive that the primary result of the chemical changes is electric current, not heat; and so in Joule's experiments with certain substances it appeared to be. More cells have since been tried, with the result that some directly heat, while others directly cool, themselves; though the bulk of their energy still seems to take primarily an electro-kinetic form.

Helmholtz has discussed the whole question from the point of view of reversibility, *i.e.* has applied the second law of thermodynamics as well as the first. Directly this mode of treatment is suggested it is almost obvious that a cell which heats or cools itself must have an E.M.F. variable with temperature, according to the law

$$\mathrm{Q}d\mathrm{E} = -\mathrm{J}\frac{d\mathrm{T}}{\mathrm{T}}\mathrm{H},$$

where H is the reversible heat generated in the cell during the passage of a quantity Q of electricity, and $\frac{d\mathrm{E}}{dt}$ is the rate of change of E.M.F. per degree at the absolute temperature T.

Hence, to investigate the sum of the reversible heat coefficients for a whole cell, it is only necessary to experiment on the variability of its E.M.F. with temperature, and to write

$$\Sigma\Pi = \frac{\mathrm{H}}{\mathrm{Q}} = -\frac{\mathrm{T}}{\mathrm{J}}\frac{d\mathrm{E}}{dt}.$$

The properly calculated E.M.F. is then not simply $\Sigma(J\epsilon\theta)$ but

$$E = \Sigma J(\epsilon\theta - \Pi).^{1}$$

In a Daniell cell it happens that dE/dt, and therefore also $\Sigma\Pi$, is very nearly 0.

It is true that with voltameters a difficulty is often experienced, in reconciling the theoretical conclusion that a certain minimum E.M.F. is essential to the decomposition of a given substance, with the practical observation that any E.M.F., however small, can cause a constant leak through an electrolyte; but it has been pointed out, at sufficient length already, how all this is capable of easy explanation by means of secondary chemical reactions.

For remember that θ is the thermal value of the reaction which actually goes on. Now if the action is such as permits the ions to dissolve in the liquid, or to recombine indirectly with each other, less energy is expended, and less E.M.F. therefore required, than if they were really set free. We must not take θ as measured for one kind of reaction and try to fit it to a case where an altogether different reaction is going on.

Again it may happen (especially with intense currents such as are most easily applied by the use of small electrodes like the ends of Wollaston wire) that ions are liberated in a condition of abnormal activity, as, for instance, oxygen as ozone, antimony in its explosive condition, &c. This necessarily means greater expenditure of energy, in proportion to the thermal value of such extra activity, and accordingly a greater E.M.F. is needed to effect decomposition under these circumstances; *i.e.*, the polarisation E.M.F. rises in value, having been forced as high as 3·3 volts, in the case of dilute acid with platinum points, by Buff.

If all these circumstances are properly taken into account, I am aware of no experimental reason which need cause us to doubt the general truth of the simple law, $E = J\epsilon\theta - J\Pi$.[1]

V. Mechanism of Electrolytic Conduction.

Electrolytic conduction is, I suppose we may say certainly, a convection of electricity by the atoms of matter; but concerning the mode in which the atoms make their way through the fluid there are several hypotheses:

(1) The molecular chain of Grotthus; modified and accepted by Faraday and many others, modified further by Hittorf to explain migration.

[1] The simplest mode of writing the complete law is

$$E = J\epsilon\theta + T\frac{dE}{dT}.$$

From this it follows that if heat of combination is independent of temperature, $\frac{dE}{dt}$ must be constant too; and generally, that

$$-\frac{d^2E}{dT^2} = \frac{d(J\epsilon\theta)}{TdT}.$$

Another way of writing it is

$$E = -TJ\epsilon\int\frac{\theta dT}{T^2}.$$

Mr. Laurie (Proc. R.S.E., 1884–5) investigates the heat of combination of zinc and iodine by measuring the E and dE/dt of a zinc iodine cell.

(2) The dissociation hypothesis of Clausius and Williamson; virtually accepted by Maxwell, modified by Quincke to explain migration, and shown by Kohlrausch to explain the facts of conductivity.

(3) The electrostatic hypothesis of Helmholtz.

1. The Grotthus chain, with its postulated pairings and unpairings, is too familiar to need the smallest description. The only difference between the hypothesis as originally stated and the form in which I suppose Faraday to have held it, consists in whether the direct action of the electrodes be supposed to extend throughout the liquid, affecting and polarising every molecule in it,[1] or whether the electrodes' direct action be considered as limited to a very minute molecular range, all interchanges beyond this range being conducted on diffusion principles or by inter-actions among the fluid atoms themselves.

The only objection that may plainly be urged against the theory is that it seems to require some small force able to effect the necessary initial decomposition, and it suggests that conductivity and tenacity of composition are related to one another in some opposing manner. Facts, however, fail to bear out any such idea; conductivity and chemical tenacity seem independent of one another; and, as has been just said under head 'polarisation,' no finite force, however small, has ever been found necessary to decompose an electrolyte when really applied to it.

In other words, no polarisation exists inside a homogeneous electrolyte; *there is no chemical cling of the atoms there, but only a frictional rub.*

Such a fact as this, if well established, renders necessary *some form* of dissociation hypothesis. A Grotthus chain of quite equidistant atoms might serve, or a momentary dissociation would be sufficient, but no hypothesis which involves a tearing asunder of molecules in the *interior* of a homogeneous electrolyte can be permitted. *Herein lies the great distinction between electrolytes and dielectrics.*

2. The form of dissociation hypothesis suggested by Clausius and Williamson is well known. It supposes that the vast majority of molecules in an electrolyte are quite insusceptible to the influence of electrodes, but that a few of them (the number being increased by complexity of composition and by rise of temperature) are, by collision or otherwise, dissociated, and exist in the free atomic state, each atom with its appropriate charge. These alone feel the influence of the electrodes. According to some statements of this hypothesis the direct influence of the electrode is supposed to reach every dissociated atom in the fluid; according to another the direct electrode action extends only to those atoms which come within a minute range of its surface, everything else being managed by ordinary diffusion, *i.e.*, by the ordinary chance locomotions common to all atoms in a fluid.

Individual atoms, though permitted to recombine as soon as they like, on this theory, are commonly thought of as existing in the dissociated state for a finite time. If there are chemical or other objections to such a view, it need not be held; all that the facts of electrolysis require is the most momentary dissolution of partnership, a temporary but quite perfect freedom, so that the feeblest possible influence may suffice to induce recombination in a definite direction and with some atom other than its former partner. Provided a sufficient supply of such

[1] Grotthus in 1805 supposed electrodes to attract ions according to an elemental inverse square law.

temporary severances occur throughout the liquid, no individual atom need remain in its uncombined state for a thousandth of a second, so far as the phenomena of electrolysis are concerned. But in proportion as the dissociated atoms are few and far between, the longer must they be supposed to continue in a free condition.

Something must here be said concerning the views of Quincke and of Wiedemann on the mechanism of electrolytic conduction.

Theory of Quincke.

Prof. Quincke, adopting the dissociation view of isolated atoms, supposes the electrical charges of opposite ions to be not only opposite in sign but specifically unequal in quantity. He considers the direct action of the electrodes to reach every atom, and to propel the one set one way and the other set at a different speed the other way according to simple electrostatic laws, and thus explains at one step both decomposition and ‘migration.’ Moreover, since the charges of opposite ions are not equal they do not neutralise each other; the resulting molecules are therefore charged with a balance of one or other electricity, and get propelled either with or against the current—thus accounting for electrical endosmose.

Evidently the hypothesis is very elastic, and, if granted, explains the facts; but I must confess to an invincible repugnance to the idea of numerically unequal charges existing in the dissociated atoms of a molecule, as well as to the corresponding idea of all the molecules of an electrolyte being similarly charged.

The laws of Faraday seem to me to point so distinctly to a definite charge for every ion, depending solely on its valency in the compound from which it has just been liberated, that it would require very strong necessity to render palatable any other view. And I find no necessity at all. The inequality of charge is postulated only in order to account for the facts of migration as provisionally understood by Hittorf, *i.e.* for the assumed inequality in pace of opposite ions. Now without pressing unduly the prejudices I have ventured to suggest against such inequality in pace, I may claim to have proved that the facts of migration do not at any rate *necessitate* such inequality; and the facts of migration are all that the theory is based upon.

And as to endosmose: it seems to me very doubtful whether any tendency to electric endosmose exists except in the immediate neighbourhood of a surface; one can only *observe* it in capillary tubes and porous partitions, and it seems allied to surface phenomena in general. It has indeed been elaborately considered by Helmholtz from this point of view, along with the reciprocal phenomenon of the E.M.F. generated by the flow of liquids along tubes.

Theory of Wiedemann.

Prof. Wiedemann's theory of electrolysis is not unlike Prof. Quincke's, but it is based on contact electricity. He supposes the atoms charged by contact with each other, and the molecule charged by contact with the vessel; and, having thus obtained the needful electrifications, decomposition and endosmose naturally follow; moreover endosmose comes

out properly connected with the existence of liquid and solid contact, or surface-action.

But how does this theory explain migration? For the atoms in a molecule, if they electrify each other by contact, necessarily do so with equal quantities; and this is where the theory differs from Quincke's. Wiedemann explains the unequal rate of travel postulated by Hittorf, not by inequality in the propelling force, but (more satisfactorily as it seems to me) by a difference in the resistance met with. He would say that a hydrogen atom slips through the liquid more easily than an oxygen atom, and so gets along faster; moreover, he has conjectured, and experimentally verified within certain limits, that the ease of travelling of a given ion is inversely as the ordinary viscosity of the liquid; so that conductivity and viscosity are inverse to one another. He has further established the important and convenient fact that migration and endosmose are totally distinct things, having apparently no sort of relation to one another.

Wiedemann's theory thus chimes in beautifully with that of Kohlrausch, who postulates a specific velocity for every ion: a velocity which depends only on the nature of the liquid in which it has to travel, and the $\frac{dV}{dx}$ which drives it.

That part of his theory which asserts a connection between conductivity and limpidity is curiously illustrated by the behaviour of water (or saline or acid solutions) at different temperatures flowing through a capillary tube. It is known that hot water flows some five times as fast as cold water through a given tube. It is also known that hot water conducts much better than cold. Further, it is known that if terminals connected to an electrometer are immersed in the liquid at either end of such a tube, an E.M.F. is discovered between them, depending on the rate of flow.

Now J. W. Clark has discovered that, notwithstanding its vastly greater rate of flow, the E.M.F. of hot water is almost identical with that of cold. His untimely death has prevented his publishing this result, but when he told it and showed it me, some year or so ago, I conjectured that the observed E.M.F. must be a sort of residue of the whole generated E.M.F., being the part unable to leak back through the liquid; and I accordingly hunted up data to see whether the extra leakiness or conductivity of hot water might so nearly neutralise the E.M.F. generated by its more rapid flow as to give the same residue of E.M.F. Whether this be the true account of the matter or no, the fact is so. The empirical formula in Naumann giving the conductivity of the liquor used in Clark's experiment (it was salt and water I think), at different temperatures, contains practically the same co-efficients as that giving the viscosity of the same liquid, measured by its flow through a capillary tube.

The observation thus agrees perfectly with the theory of Wiedemann, connecting electrolytic conductivity with mechanical limpidity.

The decrease in liquid viscosity with increase of temperature is remarkable. On any kinetic theory of viscosity, as due to diffusion one would have expected it necessarily to increase with rising temperature. In a gas it does so, as is well known, but in a liquid it does just the reverse. I am unable to suggest any reason for this.

Circumstances affecting Conductivity.

There are two ways of increasing conductivity; increase of dissociation would seem to be the main cause when a weak solution is made stronger; diminished viscosity is probably the main cause when a cold solution is made hotter.

But whether the remarkable change in viscosity caused by rising temperature is essentially the same thing as what appears in electrolysis to be extra dissociation I am not able to conjecture.

Cases where the conductivity reaches a maximum at a certain stage of concentration, and afterwards diminishes as the strength of solution still further increases, are easily explained on Wiedemann's view of viscosity, combined with that of dissociation; for at first the percentage of dissociation may increase faster than does the viscosity, and so conduction be on the whole easier; while at last viscosity must increase fast enough to neutralise the advantage of whatever extra dissociation there may be. Indeed it is probable that dissociation itself may ultimately diminish, notably so for instance with nearly strong sulphuric acid, for it seems roughly to depend on heterogeneity of constitution.

It may be plausibly argued that the experiments of Kohlrausch and Grotrian support the following view. Dissociation, and therefore also conductivity, falls to a minimum whenever the proportion of ingredients present are such as to make a very simple typical compound, such as (markedly) H_2O, or H_2SO_4, or even H_2SO_4, H_2O; but, with intermediate proportions, a certain number of semi-detached radicles are mixed along with these more stable compounds, and high conductivity is the result.

Theory of Kohlrausch.

The fundamental assumptions underlying the beautiful theory of Kohlrausch are the same as those adopted by Wiedemann. He considers electrolytic conduction performed by dissociated atoms, each of which carries the same numerical charge of electricity, one set positive the other set negative. He follows Quincke in considering their motion due and proportional to the slope of potential $\frac{dV}{dx}$; and he accounts for migration by unequal speed of travel. But—and this is the special Kohlrausch idea—every ion is supposed to have a specific velocity, in a given fluid, when urged by a given slope of potential; a velocity wholly independent of all other circumstances. Moreover, all very dilute solutions are found to behave similarly, so that an ion's rate of travel is nearly independent of the nature of the dissolved substance so long as there is not sufficient of it to interfere with the general aqueous nature of the liquid.

Kohlrausch has further shown how to calculate this specific ionic velocity in absolute measure, from conductivity, concentration, and migration, data. And the following table, taken from Clerk Maxwell's 'Elementary Electricity,' embodies some of his results.

Specific Velocity of different ions in centimetres per second when urged in a very watery solution (i.e. *one whose viscosity differs very little from water, no matter what acid or salt is being electrolysed in it*) *when urged by an E.M.F. of one volt per centimetre: according to Kohlrausch.*

Cations:	H	K	Am	Na	Li	Ba	Sr
	·0029	·00051	·00049	·00032	·00020	·00033	·00030
			Ca	Mg			
			·00025	·00022			
Anions:	I	Br	Cl	F	N_2O_3	Cl_2O_3	$C_2H_3O_2$
	·00058	·00056	·00053	·00031	·00050	·00038	·00023

It is only with much misgiving that I venture to criticise so admirable a theory supported by close agreement with experiment; but it seems less dangerous to hesitate unduly over a true theory, than to accept too hastily a false one.

In the expectation that the objections I urge against the entire and comprehensive truth of this doctrine of specific atomic velocity will be speedily met and shattered I proceed to state them.

In the first place I proceed to draw a radical distinction between the *sum* of the velocities of opposite ions and their individual velocities. Even if we admit provisionally that the sum of anion and cation velocities can be calculated from conductivity data, I demur at the partitioning of this velocity u into two unequal portions and affixing a definite velocity to either ion. The only data existing for such apportionment of u, into nu and $(1-n)u$, are the migration data of Hittorf; and I have shown at some length that all the observed facts may be otherwise explained: I even venture to think, *must* be otherwise (or to some extent otherwise) explained.

But, passing over this point, there are doubts about the sufficiency of our present data for u itself. The Kohlrausch theory considers the dissolved salt as the sole electrolyte; it neglects the conductivity of the water.[1] Let us therefore start *de novo* and independently.

Attempt at calculation of absolute ionic velocity.

Let n equal the number of dissociated molecules *of the substance undergoing decomposition* in a liquid, per unit length. Let q equal the total charge (reckoning + and − together numerically), and m the mass of each molecule; and let u be the relative velocity of opposite ions with respect to each other, under the influence of a propelling force $\frac{dV}{dx}$.

Consider an element $dxdydz$. The number of active molecules in its face is n^2dydz, the number leaving it per second is $n^2dydz \cdot nu = n^3u\,dydz$. The quantity of electricity thus conveyed is qn^3udydz per second, and

[1] In the January (1886) number of *Wiedemann's Annalen*, Professor Kohlrausch gives a long account of his present standpoint. In § 20 he discusses this question of the conductivity of water, and sees reason for modifying his original view, and for admitting that in very dilute solutions water does share in the electrolysis.

He mentions, what I did not know, that part-conduction by water had been suggested by Prof. Clausius as accounting for migration; but Prof. Kohlrausch himself adheres to his old Hittorfian view of it.

the corresponding amount of travelling matter is mn^3udydz per second, so that the electrochemical equivalent of the substance is $\varepsilon = m/q$.

By Ohm's law the strength of current is $k\frac{dV}{dx}dydz$, where k is specific conductivity of the solution; hence, since the current is also the quantity conveyed per second,

$$k\frac{dV}{dx}dydz = qn^3udydz,$$

or

$$u = \frac{k\frac{dV}{dx}}{qn^3} = \frac{\varepsilon k}{mn^3}\cdot\frac{dV}{dx}.$$

But mn^3 is the number of grammes of the electrolysed or dissociated substance in a unit cube, and this we may write $N\mu$, where N stands for the number of monad gramme-equivalents of the really electrolysed substance per c.c., and μ is its molecular weight compared with hydrogen. Moreover $\frac{\varepsilon}{\mu}$ is simply the electrochemical equivalent of hydrogen, *i.e.* a constant, say η; so

$$u = \frac{k}{N}\cdot\eta\frac{dV}{dx}.$$

We see then that for a given slope of potential u varies only with $\frac{k}{N}$, or, as Kohlrausch would put it, with conductivity $\div$ concentration, which latter he has proved within certain limits to be nearly constant for many salt solutions.[1]

But the question now arises, is N really simple concentration? What is the substance really undergoing electrolysis? Kohlrausch considers that in weak saline or acid solutions it is the dissolved salt or acid only, and he appears to consider that every molecule of this is effective; hence he would say N is at once determined by knowing how much stuff has been dissolved per litre. Take an example:

A 5 per cent. solution of ammonic chloride contains about ·001 gramme equivalent of the salt per c.c. (*i.e.* say 53 grammes per litre); and it has a conductivity about 9×10^{-6} that of mercury at 0°, or say 10^{-10} absolute units. The E.C.E. of hydrogen is 10^{-4}; so then we can easily calculate the sum of the ionic velocities for the AmCl molecule in such a solution, *on the hypothesis that it is the sole effective compound present, and that the whole of it is effective*—

$$u = \frac{10^{-10}}{10^{-3}}\cdot 10^{-4}\frac{dV}{dx} = 10^{-11}\frac{dV}{dx}.$$

[1] Kohlrausch's latest statements make k/N (understanding N in his sense *pro tem.*), a linear function of $\sqrt[3]{N}$, *i.e.* of the distance between molecules; but the plotted lines showing this are after all very curved, and all that the facts really amount to is, I think, that

$$k = a + bN + cN^2 + \&c.;$$

where a, being the conductivity of pure water, may be taken as zero. The N here interpreted in Kohlrausch's sense, as representing the amount of dissolved salt, I call henceforth N′.

Let the slope of potential be one volt per centimetre, *i.e.* let $\frac{dV}{dx} = 10^8$, then $u = \cdot 001$; and this agrees exactly with Kohlrausch's value; only he apportions it ·00049 to Am, and ·00053 to Cl, upon Hittorfian grounds, instead of half to each.

Ignoring this last mere migration question, what is there hypothetical about the arithmetical problem? Plainly the nature of the substance conveying the current; *i.e.* the value of N.

If what I have said under head 'migration' has any weight, the current is really conveyed partly by the dissolved substance and partly by the solvent, in the proportion of λ to $1 - \lambda$. Let us reconsider the above investigation from this point of view.

Very little change need be made; we shall have n_1^3 and n_2^3 for the number of dissociated molecules of the two substances per c.c., and u_1 and u_2 for their respective ionic velocities. The ratio in which the two substances conduct the current will be $n_1^3 u_1 : n_2^3 u_2$; and corresponding to n_1^3 and n_2^3, there will be N_1 and N_2 to represent the amount of dissociated substance present, reckoned in gramme-equivalents per cubic centimetre of solution; but q remains of the same value as before, and equal to $\frac{N_1}{\eta n_1^3}$ or $\frac{N_2}{\eta n_2^3}$.

So the equation between two expressions for intensity of current becomes

$$k \frac{dV}{dx} = q\,(n_1^3 u_1 + n_2^3 u_2) = \frac{q}{\lambda}\, n_1^3 u_1 ;$$

or

$$u_1 = \frac{\lambda k}{N_1} \cdot \eta \frac{dV}{dx},$$

and

$$u_2 = \frac{(1 - \lambda) k}{N_2} \cdot \eta \frac{dV}{dx}.$$

The value of λ is determined by migration experiments, in the way already explained, and k of course is known; but, since there exists no known means of ascertaining the value of N_1 and N_2, there remains complete uncertainty as to the absolute values of u_1 and u_2; all that one can determine, from conduction and migration data combined, are the values of $N_1 u_1$ and of $N_2 u_2$.

On Kohlrausch's hypothesis, taking the suffix 1 as applicable to dissolved salt, λ is supposed to be 1, and u_2 accordingly 0; moreover, since *every* molecule of the salt is supposed by him to be dissociated sufficiently to take part in the conduction, N_1 is considered known from concentration data, *i.e.* from the percentage of salt contained in the water, and thus u_1 is calculable.

Permitting ourselves to doubt all this, we come to the conclusion that we do not yet know the absolute velocity of any ion, and cannot know it without further information regarding the dissociation ratio (that is, N_1/N', or N_2/N') of each substance present.

On the unlikely supposition that this criticism be in any sense accepted, what is the meaning of the striking agreement between Kohlrausch's theory and experiment?

His view leads to the equation

$$k\eta \frac{dV}{dx} = N'u,$$

where N' is the total number of monad gramme-equivalents *of the dissolved substance* in a cubic centimetre of solution.

Our view, on the other hand, leads to the equation

$$k\eta \frac{dV}{dx} = N_1 u_1 + N_2 u_2,$$

where $N_1 + N_2$ represents the (unknown) amount of *actually conducting substance* per c.c. of solution.

Now it seems by experiment that k/N' is an approximate constant,[1] at any rate for weak solutions; so we must suppose the fact to mean that $N_1 u_1 + N_2 u_2$ is, within limits, nearly proportional to N'.

It is in no way surprising that the dissociation of both substances should proceed *pari passu* with, and be initially proportional to, the quantity of stuff added to the water; but there remains a further question, which, if I am able to discuss it, shall be considered elsewhere.

Theory of von Helmholtz.

Finally we come to the wide-reaching theory of Helmholtz.

The root idea of this theory is that each kind of matter has a specific attraction for electricity, some kinds for positive, other kinds for negative; that, accordingly, work must be done to separate an atom from its electrical charge, or to remove electricity from an atom of high specific attraction and give it to another lower in the scale. Further, that chemical affinity is mainly due to the electrical attraction of oppositely charged atoms, and that when such atoms combine into a compound molecule they do not discharge into each other, but retain their charge.

Apply this principle to a Daniell cell.

During the action of the cell a certain amount of positive electricity has to leave (deposited) Cu, a substance which attracts it feebly, and enter into union with (dissolved) Zn, a substance which attracts it much; hence is derived the energy or E.M.F. of the cell.

Apply the same principle to a water voltameter. During the passage of a current the charges are torn from hydrogen and oxygen atoms and given to the electrodes, which, if they are platinum, have no special attraction for either electricity; hence arises the E.M.F. of polarisation, or the work needed to decompose the liquid. Work is done, according to this theory, not in tearing the atoms asunder, but in tearing their electric charges from them. If the ions are allowed to enter into combination with some available radicles, in such a way as to retain their charges, polarisation E.M.F. is much reduced. So long as the atoms have not given up their charges they cling to the electrodes and cannot be removed mechanically, say by exhaustion or the like; but if once their charges are given up and molecules of the single substance formed, it makes but little difference to polarisation whether that substance be allowed to dissolve in the liquid or be made to bubble up from it.

But it is to be understood, I believe, that in estimating E.M.F., or effective energy of a cell per unit electricity conveyed, Helmholtz would take into account the energy of all secondary, as well as of all primary actions, 'minor attractions of solvents' as well as affinities of ions.

Helmholtz points out that the interior of an electrolyte can stand not the slightest electrostatic strain, and hence, in so far as a voltameter

[1] See, however, a previous footnote.

behaves as a condenser, it does so by reason of actions going on within the films or boundaries separating the liquid from the electrodes. From observations made with his air-free cell Helmholtz estimates the thickness of these quasi-dielectric films as 10^{-8} centimetre—the customary molecular magnitude.

It seems to me that Helmholtz accepts the possibility that ordinary electrostatic laws may be applied to the interactions of atoms and their charges, and to the attractions of atoms by the electrodes across this thin molecular film. And he points out that the reason so feeble an E.M.F. is sufficient to effect decomposition is just because of the extreme thinness of the film—the slope of potential dV/dx being by no means insignificant.

Helmholtz shows that the analogue between the pre-decomposition state of a voltameter and a condenser of constant capacity is accurately sustained by his air-free cell, charge being proportional to potential down to $\frac{1}{1000}$ volt or perhaps lower; and this fact he considers to prove that by far the greater part of the force binding atoms together, and probably the whole of it, is electrical; for 'if any chemical force bound ions together, requiring work to overcome it, an inferior limit ought to exist to such E.M.F.s as are able to attract ions to the electrodes and charge them as condensers. No indication of any such limit has yet been discovered.'

But while he thus considers it proved that the mightiest chemical forces are really electrical, he by no means denies the existence of others. Atoms cling to electricity, and charged atoms cling to one another, but uncharged atoms may cling somewhat, and this may be the distinction between 'typical compounds' and 'molecular aggregates.' This distinction had been forced upon me also independently, and so I quote it with full agreement. All electrolytes belong to the 'typical compound' class, and it is by means of the charges in these atoms that they are so easily decomposable, notwithstanding their strong affinities. But combination can occur between elements of very weak affinity, which only with difficulty can be got to unite; and yet, once combined, they seem to cling with the most surprising tenacity. These bodies, I should suppose, are molecular aggregates held together by purely 'chemical,' *i.e.* material or non-electrical, forces; and the reason of their apparent tenacity is, I would suggest, merely that they afford no handle to lay hold of. They are quite unsusceptible to electrical influence, unless it be in the violent and perhaps thermal form of the electric spark. If I instance such bodies as cyanogen and ammonia it is only to indicate more suggestively what I mean.

I do not feel sure whether Helmholtz would lend his name to the suggestion just made, for he hedges a little about these molecular modes of combination and says, 'But the fact that even elementary substances with few exceptions have molecules composed of two atoms makes it probable that even in these cases electric neutralisation is produced by combination of two atoms each fully charged, not by neutralisation of every single unit of affinity.' I venture with great deference to suggest, as an objection to this view, the fact that charged (say hydrogen) atoms are unable to unite with each other, though they attack everything else with vigour, but that so soon as they are allowed to give up their charges to an electrode they at once unite and become molecules of gas.

I need not stay to do more than remark that the notion of an attraction between matter and electricity is made by Helmholtz to explain a great many other things—'contact E.M.F.,' 'thermo-electricity,' 'frictional electricity,' and, in fact, all electrostatics and most of current electricity.

These things appear in a great many of his writings, first in his great Memoir of 1847, but they are conveniently summarised in his Faraday Lecture of 1881, from which I have just now been quoting.

It is scarcely decent to obtrude my own opinion on so fundamental a subject as this, but I may be permitted to say that if one does grant such an attraction, and if one further conceives positive and negative electricity as the two constituents of ether, not only chemical affinity but specific inductive capacity and refractive index, together with the Fresnel-Fizeau connection between ether and matter, can be readily conceived and, so to speak, accounted for; and the attraction of gravitation does not lag far in the background. Seven years ago I spent some time endeavouring to set out all these things in a systematic and pretentious form, but I came to the conclusion that the task was beyond my strength. The special things which Helmholtz more particularly explains by his theory—viz. contact E.M.F., thermo-electricity, and frictional electricity—did not suggest themselves to me in such a direct connection with it; nor do they now.

The theory of Helmholtz insensibly impels one to try to apply ordinary electrostatic considerations to the interactions of atoms and to the effect of electrodes upon them. It suggests, in fact, a theory of chemistry; in the form of a sort of supplementary kinetic theory of gases with electrified atoms. But the liquid state, which (more than ever by recent researches[1]) seems essential to chemical action, has difficulties of its own to be overcome before the behaviour of electrified atoms can be properly treated.

It may be noted that whereas the actual force of attraction between two atoms at a distance like 10^{-9} is not great, being something like 10^{-4} dyne, the acceleration produced by it in the small mass of an atom is terrific, being nearly a trillion times that produced in ordinary bodies by the earth. To show that mechanical forces are insignificant compared with electric ones between charged atoms, Helmholtz reminds us that their electric attraction at any distance exceeds their gravitative attraction at the same distance nearly a hexillion times.[2]

[1] Those of Mr. Dixon and others on combustion and on gaseous combination or explosion. As Professor Armstrong has pointed out, they seem to suggest a necessity for the presence of a dissociated typical compound, *i.e.* for electrically charged atoms (see above), in every reaction. Should this turn out to be a fact, it will be one of profound chemical and physical interest.

[2] This is not exactly Helmholtz's way of putting it (Faraday Lecture, 1881), but it comes to the same thing; and it is perhaps as well to notice that there is nothing uncertain about the calculation: the least accurately known datum in it is the gravitation constant, or the earth's mean density. The general expression for the ratio between the electric attraction of two radicles in an electrolytic compound and their gravitative attraction, at any given distance, is

$$\frac{V^2}{4\gamma\mu_1\mu_2\eta^2};$$

where V is the velocity of light, η the electro-chemical equivalent of hydrogen, γ is the gravitation constant, gR^2/E, or $\frac{3g}{8\rho\times10^9}$, while μ_1 and μ_2 are the combining equivalents of the radicles in the compound compared with hydrogen; or $\mu_1+\mu_2$ is the compound's ordinary 'molecular weight' divided by its 'atomicity': *e.g.* for water, $\mu_1\mu_2=8$; for copper sulphate, 80; for silver nitrate, 6696.

The numerical value of the above ratio is

$$\frac{10^{35}}{3\mu_1\mu_2}.$$

VI. Addenda.

Electrostatic calculation of E.M.F. needed to effect decomposition, (a) *of an electrolyte,* (b) *of a dielectric.*

(*a*) I do not think the process is justified by anything Helmholtz has said, but I have allowed myself to reckon through what atomic distances mutual electrical attraction of two charged atoms might be overcome by means of an electrode differing in potential from a liquid by, say, a volt, *i.e.* by means of a slope of potential of 1 volt in 10^{-8} centimetres.

Let y be the effective distance between two oppositely charged atoms in a molecule, so that the force between them is $\frac{q^2}{y^2}$, and let this molecule come within range of the electrode, and so under the influence of the separating stress $q\,\frac{dV}{dx}$; then decomposition will be effected when

$$q\,\frac{dV}{dx} = \frac{q^2}{y^2},\ \textit{i.e.}\ \text{when}\ y^2 = q\,\frac{dx}{dV}.$$

Taking therefore $q = 10^{-11}$, and $\frac{dV}{dx} = \frac{\frac{1}{300}}{10^{-8}} = \frac{1}{3}10^6$, y comes out 10^{-9} or thereabouts—a very respectable atomic distance. This perhaps indicates that, within molecular range of either electrode, actual decomposition or tearing asunder of molecules may occur, but that through the rest of the liquid the action is propagated in some other way, *e.g.* by a divorced atom being projected so close to one of the constituents of a molecule as to combine with it in place of its former partner, and so on.

In this way two postulates may be avoided—1st, the existence of continuous dissociation in ordinary liquids unexposed to electrical influence, a hypothesis to which I understand chemists see some objections; and 2nd, the attraction of matter for electricity postulated by Helmholtz, so far as it is necessary to the explanation of polarisation. Polarisation would then really be the E.M.F. needed to tear asunder molecules of the given compound within molecular range of the electrode; and automatic interactions of the molecules must be trusted to carry the action forward throughout the whole mass.

It appears that on this hypothesis an E.M.F. of one or two volts would be sufficient to decompose acid water, or other similar compound, if atomic distance were something comparable with 10^{-9}. But it may be considered that the magnitude of this distance points to something like at least incipient dissociation as necessary to electrolysis. Let us find its value more carefully.

Put the problem thus:

To find the relation between molecular distance, x, and the least distance at which atomic electric attraction can be overcome by a slope of potential of 1 volt per x centimetres; on the hypothesis that ordinary electrostatic laws are applicable.

$$\frac{V}{x}\,q = \frac{q^2}{y^2}.$$

But $$q = 1{\cdot}5 \times 10^{13} \,.\, x^3,$$

and $$3 \times 10^{10}\,V = 10^8,$$

so $$\frac{q}{V} = 4{\cdot}5 \times 10^{15} \, . \, x^3,$$

and $$y = {\cdot}67 \times 10^8 \, . \, x^2.$$

The most probable value of x at the present time is, I suppose, $\frac{1}{2}\,10^{-8}$; and the fact that y comes out so nearly equal to x is at least noticeable.

Distinction between electrolytes and dielectrics.

Homogeneous electrolytes and dielectrics behave very similarly, when supplied with electrodes at slight difference of potential, but the distinction is that, whereas in an electrolyte the whole of the strain is thrown upon a pair of thin films, the bulk of the medium being as quiescent and unstrained as a metal, in a dielectric the strain exists throughout the medium, sloping steadily down from anode to cathode; if these terms be still permissible. In the one therefore the $\frac{dV}{dx}$ strain is excessive, and very small differences of potential easily cause decomposition; in the other, the strain on each molecule is insignificant—there being a whole series of them to share it—and accordingly it takes a great difference of potential to effect decomposition, or disruptive discharge as it is in this case called, especially if mechanical locomotion of the medium, or a chain of dust particles, be avoided.

In rare gases it seems likely that, by a locomotion of molecules, a steady convective discharge can be maintained, distinct from true disruption; indeed mobility of particles may play an important part in the giving way of any fluid. But, ignoring this, we can reckon roughly on electrostatic principles how much E.M.F. a given thickness of a dielectric ought to bear; and this is what, at the beginning of the present section, I call

(*b*) *Calculation of E.M.F. needed to decompose a dielectric.*

Let the distance of the plates be z; there will be a series of $\frac{z}{x}$ molecules to share the $V-V'$ between them.

Now, since there are about 10^8 molecules per linear centimetre in a liquid, and about 10^9 in an ordinary gas, the slope of potential in a dielectric will be some 10^{-8}th of what it is in the films of an electrolyte for the same potential difference; and accordingly, since it takes one or two volts to decompose a liquid, it will require one or two hundred million volts per centimetre to burst a liquid dielectric, and a tenth of this for a gas. This is probably much too high—certainly it is for a gas; but then what is one to think about the electrification of the atoms of a simple gas like nitrogen? The hint of Helmholtz occurs to one, that possibly even molecules of elements possess some electric charges; and if one could fancy that the atomic charge in such molecules, instead of being 10^{-11}, was something like 10^{-16}, the experimental value of the dielectric strength of air (*viz.* 33,000 volts per centimetre) would be obtained, on the preceding hypothesis; and it would vary with the cube root of the pressure.[1]

[1] On any such theory, the bursting potential will vary as the number of molecules in a row between the plates, *i.e.* as the cube-root of the pressure in the case of a gas. This is by no means true for the potential required to *begin* discharge, but it is not hopelessly out of accord with some measurements by Röntgen (*Wied. Elek.* iv. 465) of the minimum potential sufficient to maintain a discharge already begun

Probably, however, one is now not on the right track, and it is better to refrain from further guess-work; though I must just point out that if one reckons the distance at which fully charged atoms would be able to cling together, on this hypothesis, if they are to give ordinary dielectric strength, though it is too great to be reasonable, it is not outrageously so. The simplest plan is, perhaps, just to quote the arithmetic.

To reckon the greatest atomic distance when the atoms of a molecule are just being torn asunder electrically. Call it y.

The actual stress which can be supported by ordinary air, according to experiment, is given by the equation

$$\frac{V^2}{8\pi z^2} = p = \tfrac{1}{2} \text{ gramme weight per unit are}$$

so a centimetre thickness can stand V = 110 electrostatic units, or 33,000 volts.

This would give a force of 110 dynes per electrostatic unit, or $110 \times 1{\cdot}5 \times 10^{-11} = 1{\cdot}65 \times 10^{-9}$ per atom.

The attracting force of two atoms, at distance y, is $\dfrac{2{\cdot}2 \times 10^{-22}}{y^2}$.

So when a molecule is on the verge of giving way,

$$y^2 = \frac{2{\cdot}2 \times 10^{-22}}{1{\cdot}65 \times 10^{-9}} = 1{\cdot}33 \times 10^{-13},$$

or $y = 3{\cdot}65 \times 10^{-7}$ centimetres, when just giving way.

This is for common air, and is much too big: a stronger dielectric will be satisfied with a smaller limiting atomic range, though still not with one small enough.

It is difficult to suppose that *molecules* tend to get separated instead of *atoms*, and that accordingly ordinary mechanical, not chemical, tenacity is the force to be overcome in a dielectric; for how can this apply to the case of a liquid or a gas?

in pure dry air: as the following table shows. Though indeed the *fourth* root of the pressure would do better still.

Minimum Potential	Pressure	$\frac{V}{\sqrt[3]{P}}$
639	615	75
577	499	73

Consequences of an atomic theory of electricity. Possible electrostatic saturation.

The fact that atoms in electrolytes have a constant charge which is the same for every kind of atom, or at least can only be multiplied by an integer, is so striking, that one is constrained to think whether electricity is something necessarily associated with atoms of matter, whether all electrical actions are simple electrostatics among the atomic charges, and whether no quantity of electricity smaller than an atomic charge can exist.

The notion is repugnant, but it just wants considering; though I should hardly have ventured to suggest it but for the support Helmholtz has given to the view as at least a possible one (see above).

The first difficulty which meets us is the serious one that, since air and gases are not electrolytes, nothing is known about the atomic charges of their molecules.

On the atomic theory, however, the unit of electricity is about 10^{-11}, and nothing smaller is possible; so we must provisionally use this as applicable even to air atoms; for it is hardly reasonable to suppose that the aqueous vapour, or other true compound, present is essential to electrostatic actions.

Consider a centimetre cube of air at pressure p dynes per sq. cm.; the number of atoms in it is $\frac{p}{10^6} \cdot \frac{n^3}{800}$ or say $10^{15}\ p$.

The number in each face of the cube is $10^{-6} n^2\ p^{\frac{2}{3}}$, or $10^{10}\ p^{\frac{2}{3}}$.

The available quantity of electricity of either kind on a face of the cube, *when every molecule is fully polarised*, is therefore

$$10^{10}\, p^{\frac{2}{3}} \times 10^{-11} = \frac{p^{\frac{2}{3}}}{10} \text{ electrostatic units.}$$

This is therefore the maximum possible density to which an air condenser could be charged, on the atomic theory.

If p is a millionth of an atmosphere, this gives 400 volts per centimetre as the maximum possible.

If p is 1 atmosphere, it gives 4,000,000 volts per centimetre.

A *liquid* condenser would have 400,000,000 volts per centimetre as its maximum charge.

It is to be understood that this calculation has nothing to do with the dielectric strength of the medium. It is not considered whether the medium can *stand* this stress or not; all that is reckoned is the maximum that can possibly be *produced*, on the atomic hypothesis.

If every dielectric refuses to stand anything like so much, it is difficult to test the hypothesis; but if the maximum possible were to come out something comparable with what a substance under certain conditions can stand, then it may be possible to try the experiment and to discover some evidence of the existence of an upper limit to the charge a condenser, made of that substance, is able to receive.

One effect naturally suggests itself. If the maximum possible charge is insufficient to burst a given kind of condenser then that condenser cannot be burst—it will behave as if infinitely strong.

Now if what I have said has any sense (an improbable assumption) the law of variation of maximum charge with pressure, in a gas, is as $p^{\frac{2}{3}}$.

The dielectric strength of air is ordinarily far below the maximum charge, but if it varies with pressure more rapidly than the $\frac{2}{3}$ power, say as p—it follows that at some high pressure it will overtake the maximum charge and pass above it; and in that case an air condenser at some very high pressure would be unburstable, *i.e.* the dielectric strength of sufficiently high-pressure air would be infinite.

On the other hand if dielectric strength were to vary say as $p^{\frac{1}{2}}$, then very low-pressure air would possess this property.

Experimental evidence tends to show that, over a moderate range, dielectric strength varies roughly as p; but that at very low pressures this law is largely departed from, dielectric strength rapidly falling to a minimum and then apparently increasing again as the exhaustion proceeds.

Cailletet found that air at 50 atmospheres was tremendously strong, a millimetre of it being able to resist a powerful induction coil.

But it is well known that high vacua are apparently very strong too; though the latter is open to a doubt suggested by Schuster, who does not feel sure that the potential applied to small electrodes is really communicated by them to the gas.

Another mode of attacking the question, whether an upper limit to charge exists, would be by seeking for a diminution in the capacity of a condenser when highly charged. It is generally assumed that the capacity of a condenser is a constant quantity; but perhaps our evidence for this is at present insufficient. The electrostatic permeability of a medium (*i.e.* its specific inductive capacity) may be found to diminish with high strain, and tend toward zero, in other words, a dielectric may become 'saturated with electricity,' just as magnetic permeability tends towards zero in a substance very highly magnetised or nearly 'saturated with magnetism.' Unless it has been already done, condensers of various material (and air is the easiest) ought to be examined over a very great range of absolute potential; for a departure from the law of simple proportion between charge and E.M.F. could not fail to have an important signification, whether it be the signification I have hinted at or no.

In conclusion, I must confess that the latter portion of this communication has been perhaps too widely speculative; and it behoves me to explain that only a small portion of the whole paper was spoken by me at the meeting of the Association in Aberdeen; and that in ordering it to be printed *in extenso* the Committee have not made themselves responsible for the contents of the whole. I judged, however, that a little latitude would naturally be allowed in the opening of a discussion, and have therefore set down all the matters which, had time and convenience served, I was prepared to bring forward. The preliminary notes published in 'Nature,' September 10, 1885, will accordingly now serve as a table of contents. I expect my suggestions to receive a severe and salutary criticism, but trust that my admitted ignorance of much that has been done may be pardoned, for it is to be remembered that I was not called upon to draw up a conclusive Report, but to furnish food for reflection and discussion.

List of Suggestions.

It seems permissible and convenient to print here the list of suggestions issued, soon after the meeting, to the Committee appointed jointly by sections A and B, 'for the purpose of considering the subject of Electrolysis in its Physical and Chemical bearings,' in case they might aid any member in deciding on a special subject of investigation.

Some of the statements have been slightly amended; Nos. 11 and 12 have been added.

1. *Is Ohm's law exactly true for Electrolytes?*

We know that it is roughly true for many electrolytes within certain rather wide limits of possible experimental error, but its *exact* verification for any one electrolyte has not yet been attempted, and it is very important. The question is whether, eliminating all effects due to rise of temperature, the resistance-coefficient of an electrolyte is absolutely constant for infinitesimal, ordinary, and powerful currents.

There are two or three plausible ways in which a discrepancy from the exact law may be expected to arise.

(*a*) Supposing the ions absolutely dissociated and to make their way through the liquid according to customary laws of fluid friction, propelled as it were by the electric forces, as is assumed in the theories of Wiedemann, Quincke, Kohlrausch, and others, then so long as the frictional or viscous resistance they meet with varies simply as their velocity, Ohm's law is obeyed. But for very strong currents it is possible that the fluid friction may vary according to a higher power of the speed, and if so, the E.M.F. needed to drive a given current would be a little higher than that calculated from Ohm's law.

(*b*) If the ions are not absolutely dissociated, but exhibit a trace of chemical cling, then some finite though small E.M.F. may be needed to start a current, and thus a violation of Ohm's law may occur in the same direction as that already suggested, but most noticeable with infinitesimal currents. Helmholtz has shown that, for ordinary dilute acid, such an effect, if existent, is almost too small for observation; but in some worse conducting liquids it might conceivably be found.

(*c*) Very viscous or highly resisting electrolytes, such as glass, water, turpentine, &c., may show some discrepancy. In fact, this may be treated as a separate question, and asked thus:

2. *Is Ohm's law obeyed by very bad conductors?*

In other words, is the rate of leakage from a charged electrometer simply proportional to the potential with which it is charged, no matter what kind of slight earth connection is established? Polarisation E.M.F.s are in this case probably too small to have much influence, and so the problem is in some respects simplified. The investigation is in fact precisely similar to an examination of the accuracy of Newton's law of cooling.

Surface films.

Among bad conductors, the films on the surface of glass rods are to be remembered and studied. It would be interesting to know the absolute resistance of some such films, if it be possible to specify their conditions.

Optical observations, combined with electrical conductivity determinations, like those of Reinold and Rücker with soap-films, may be expected to lead to further knowledge of their thickness, nature, &c.

A hygrometer founded on the resistance of such films would perhaps indicate not what is ordinarily called the 'humidity' of the air, *i.e.* its nearness to saturation, but its actual vapour pressure.

Possible methods of answering Question 1.

I find it difficult to make useful suggestions with regard to an experimental attack on the question of Ohm's law in electrolytes.

It is to be remembered that experiment is useless except on a very good and well-considered plan. Something like 1 in 1,000 accuracy must be obtained, and higher may be aimed at.

Although the best experiments hitherto are probably those of Kohlrausch and Nippoldt with alternating currents, it does not seem to me that such currents, employed with electrodes, are suitable for a really accurate determination. The capacity of polarisable electrodes is enormous, and apparently instantaneous, and the use of alternating currents by no means avoids effects due to this polarisation; although it is possible very nearly to eliminate these effects by calculation, as Kohlrausch did.

Methods of avoiding all polarisation, by working in closed circuits wholly electrolytic, are tempting. Such, for instance, as the damping effect, when a magnet swings over a liquid, or when a vessel of liquid is spun between the poles of a magnet (*e.g.* Guthrie and Boys).[1] The electrolyte may be made to partake of the motion of the vessel by using a jelly. But the calculation of such experiments would (to me, at any rate) be difficult, and it is not likely that the experiments themselves are susceptible of minute accuracy.

Probably the best plan of research would be some modification of the ingenious method planned by Maxwell for the British Association Committee on Ohm's law in metals. (See Brit. Assoc. Report, Glasgow.)

If perfectly similar tapping electrodes could be got, it would be sufficient to compare the E.M.F.s at the ends of two troughs or tubes, one wide, the other narrow, placed in series, so that the same current might flow through both. A null method of comparing E.M.F.s is simple enough. For instance, a liquid Wheatstone bridge might be made, one branch consisting of the very wide and very narrow tubes, the other of a uniform tube or trough of moderate width (see figure). A and B are battery electrodes, while C and D, which are carefully chosen, make connection with an electrometer; C being movable. A galvanometer seems dangerous, as allowing slight currents which might disturb the equality of the tapping electrodes.

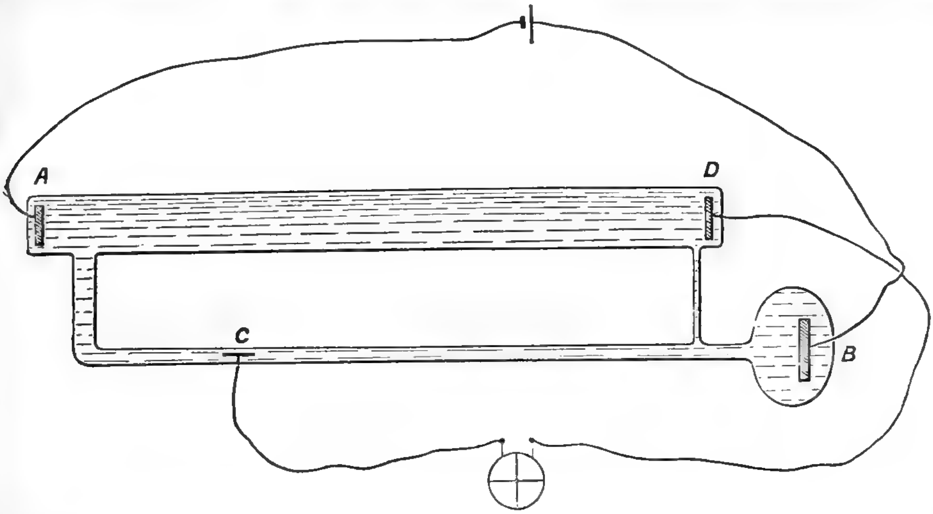
The liquid employed might be chosen for convenience, and a natural liquid to use would be sulphate of zinc, with amalgamated zinc electrodes. It is not to be assumed that the polarisation of these is really nil, but it is certainly feeble, and will thus diminish the uncertainty and risk of error attending the experiment.

To avoid difficulties due to the inevitably unequal rise of temperature, an intermittently strong and weak current can be employed as in the Maxwell-Chrystal method[2] (cf. Schuster, Brit. Assoc. Report, Belfast).

[1] *Proc. Phys. Soc.* or *Phil. Mag.*, 1879 and 1880.

[2] *Brit. Assoc. Report*, 1876, p. 36, Glasgow.

If any positive discrepancy were obtained, it would be necessary to consider to what it was due, and whether the effect of *surface* had anything to do with it. The fine tube might, for instance, be replaced by a



tube packed full of thin glass rod so as to have about the same capacity but much more surface.

3. *Are Electrolytic and Metallic Conduction thoroughly distinct, so that no substance has a trace of both conductivities at once?*

In other words, has any electrolyte a trace of metallic conductivity? or can any compound metal experience a trace of electrolysis? Is electricity able to slip through or among ions, instead of necessarily propelling them; and is it able to do both things at once? A positive answer to this question need not be given in the form of a disobedience to Ohm's law, for there is no reason for supposing that a metallic slip of electricity through the ions would be more prominent with small than with great current intensity.

Insufficient polarisation E.M.F., and constant leakage of a current against it, are the facts which have caused many experimenters to suspect such metallic slip; but secondary actions would so easily account for the same thing, that it is necessary to be extremely cautious in interpreting such observations. Helmholtz's air-free cell proves that if any effect of the kind takes place it must be excessively small for ordinary acid (Faraday lecture). Clark's experiments show that no such explanation of the behaviour of certain anomalous fused salts is *necessary*.[1] But it is impossible to give a certain negative answer to the question, on experimental grounds, until every substance has been tried with minute quantitative accuracy. A positive answer for any substance would of course be a denial of the applicability of Faraday's law to that particular electrolyte.

The second half of the question,

Can any metallic alloy conduct electrolytically?

seems easier of attack.

Experiments have been made, on tin and lead, potassium and sodium,

[1] *Phil. Mag.*, June 1885.

sodium and mercury, gold and mercury, cast-iron, with negative results so far.[1] But none of these alloys except sodium and mercury are well chosen. It would seem advisable to choose two metals far apart in the voltaic series, or in the thermo-electric series, so that one might cling more to positive electricity, and the other more to negative, if possible. Or they might be chosen with their so-called 'specific heats of electricity' very different. Or, again, it may be well to choose two metals differing considerably in conducting power, so that one might be rubbed along with the current, so to speak, more than the other.

I might suggest gold and lead, or copper and tin,[2] or copper and zinc, or bismuth and antimony; beside, of course, mercury and zinc, or mercury and sodium, or, again, copper and zinc dissolved in mercury &c. But it is to be remembered, from the experiments of Dr. Guthrie, Prof. Chandler Roberts, and others, that diffusion in all such cases is excessively rapid, and that precaution must be taken to diminish its effect in restoring uniformity of composition.

A U tube with a constriction at its bend might be used, the whole filled with homogeneous alloy and kept just above the fusing-point. Pass a very strong current through the U, and gradually cool down till the whole is solid, keeping the current on all the time. Then analyse the two legs, and see if they show any difference in composition.

4. *Is there any relation between Optical Opacity and Electrolytic Conductivity?*

Metallic conductors are opaque, but electrolytic conductors are, ordinarily speaking, transparent. At the same time, ordinary water is by no means so transparent as bisulphide of carbon; it absorbs a great deal of some kinds of radiation. Does this opacity increase as conductivity increases, say by addition of acid, and diminish as the water becomes purer; or is there no relation between conductivity and opacity in liquids?

Vision through long tubes is the simplest mode of attacking the question, but to get anything like a complete or satisfactory answer, the absorption spectrum of liquids in the less refrangible ultra-red region would have to be observed.

There are two obvious ways of explaining the transparency of a conducting liquid on the electro-magnetic theory. One is to assume that the minute and rapidly reversed electromotive forces which constitute light are incompetent to effect anything like alternate decomposition and recombination, so that the liquid to such forces behaves exactly like a dielectric; a supposition which would be equivalent to admitting a slight disobedience to Ohm's law, and which is a very reasonable one. The other is to assume that electrolytic conduction only occurs among *dissociated* atoms, and that these free atoms constitute so small a percentage of the total number as not appreciably to affect the transparency or dielectric character of the bulk of the liquid. On this second hypothesis, however, some slight absorption of radiation ought to be expected, and it might increase as the conductivity, *i.e.* percentage of dissociated atoms, increased.

[1] In Mr. Shaw's very useful article 'Electrolysis' in the *Ency. Brit.*, the slip is made of saying that these alloys have been electrolysed.

[2] Prof. Roberts' curious alloy $SnCu_4$ is well worth trying; see *Phil. Mag.*, Dec. 1879, p. 558.

It may be difficult to maintain perfect homogeneity if change of temperature be attempted, else, of course, warming a liquid ought, on this second hypothesis, to make it less transparent.[1]

On the first hypothesis it is possible that exceedingly intense radiation might develop an opacity in liquids quite transparent to ordinary light.

5. *Under what circumstances is solid matter deposited in the Path of a Current?*

It is known, from the experiments of Davy and others, that if at the junction of two liquids the opposite ions can form an insoluble compound, then such insoluble compound is formed, those ions drop out of action, and others have to convey the current. For instance, if a current be sent from a vessel containing a barium salt to another containing a sulphate, through an intermediate vessel containing, say, dilute HCl, then $BaSO_4$ is precipitated in this vessel. I propose to make this intermediate vessel in the form of a tube, and examine whereabouts this formation of $BaSO_4$ first appears; varying intensity of current, density of solutions, &c.; and other similar experiments. (See Question 7.)

Sir Wm. Thomson, at the meeting, made some important observations about deposits of solids in general, and about the possibility of a long-established current producing solid concretions of a nature not naturally to be expected. As, for instance, nodules of copper in the sawdust of a Menotti cell, possible accretions in the joints of animals, &c.

Some porous substance seems most likely, according to present observations, to have such crystals and nodules formed in it; and steady currents might be kept up through porous or cracked crockery, or sawdust, or sand, and secular observations made on the subject.

It is not easy to see why deposits of this latter kind should appear, except by reason of the surface action known as capillary E.M.F. and by some interference with Faraday's law; so that, for instance, the amount of copper going down current, and of SO_4 going up, should not be exactly equivalent, but a slight excess of copper be left, which has to drop out in mid-stream.

If it is allowable thus to regard some deposits as isolated ions, their study becomes of considerable interest.

6. *Is it possible for opposite corresponding Ions to travel at different rates?*

The notion of different speed for different ions is founded upon the facts of 'migration,' but if it can be shown that migration phenomena can be accounted for in another and simple manner, all *necessity* for the hypothesis breaks down.

There only remains the fact that some solutions conduct better than others; and this may be accounted for, either by greater speed of their ions, or by a greater number of dissociated atoms able to take part in the conveyance of electricity. It affords no answer to the question as to whether the opposite radicles travel at the same or at different rates.

In favour of Kohlrausch's and the customary migration theory, it may be truly urged that it is reasonable to suppose that each ion should have

[1] It is here assumed that better conduction means more dissociation; this is not at all certain, it may mean less viscosity; and it apparently does mean this, for the case of rising temperature, though not for the case of increased complexity of constitution.

a rate of travel independent of any other from which it is completely detached; in fact, that it is difficult to see how the velocity of any given radicle can be controlled by the nature of the opposite radicle, which is travelling at its own pace in an opposite direction.

And *against* this independence of the corresponding ions I have only to urge that it would mean that an electric current could consist of *unequal* opposite currents of positive and negative electricity, and that in some cases at least this is certainly not true. Thus, in a simple fused or homogeneous electrolyte, it is quite certain that opposite ions are travelling at the same rate, and that therefore the current in them consists of *equal* opposite streams of positive and negative electricity. Now if such an electrolyte is put in series with salt solutions, and the same current sent through all, it is difficult to suppose that in one part of the circuit the current consists of equal opposite streams, and in another part of unequal; yet this is what Kohlrausch's theory necessitates.

Again, when a Holtz machine or other replenisher is used to produce a current, half the plate is carrying positive in one direction, and the other half is carrying negative in the other direction, so that in the visible convective part of the circuit it is easy to ensure the existence of equal opposite currents; and there is no evidence that the decomposition produced by such currents differs in any respect from that produced by equally strong voltaic currents.

But whence the repugnance to admitting that a current may be at one place $\frac{1}{2}$ positive and $\frac{1}{2}$ negative, and at another place $\frac{3}{4}$ positive and $\frac{1}{4}$ negative? Only from the habit of picturing positive and negative electricity as both obeying the laws of an incompressible fluid, with identity or continuity of existence, and the consequent difficulty of supposing that $\frac{1}{4}$ stream of negative electricity and $\frac{1}{4}$ stream of positive can at one point rush towards each other, meet, and disappear, leaving no trace behind of either. For this is what must happen at the junction of a fused electrolyte, in which opposite ions are going at the same pace, with a dissolved electrolyte, in which the positive ion is travelling three times as fast as the negative ion.

If there is no validity in the objection, then Kohlrausch's theory is probably true pretty much as it stands; but if any difficulty may be legitimately felt in the direction indicated, some modification must be made in Kohlrausch's theory.

7. *On the apparent relative velocity of opposite Ions.*

The facts of migration may, I believe, be accounted for by assuming that the solvent and the dissolved salt *both* conduct the current; but the result is to produce an apparently unequal velocity of ions, which has been mainly examined by subsequent analysis of the liquid near either electrode. I propose to examine it further by means of electrolytes in series:—*e.g.* noting whereabouts in the path of a current a solid precipitate, caused by uniting ions, first forms. I am, indeed, now engaged in these observations (see Question 5).

A disobedience to Faraday's law of electro-chemical equivalence might in the same way be detected, either by an escape of an excess of one ion past another with which it should wholly combine and become insoluble, or by a deposit of the excess of one ion because it finds insufficient of the opposite ion with which to combine and remain soluble.

It may also be possible to examine the speed with which an ion, starting from a vessel at one end of a long tube, makes its appearance in another vessel at the other end of it, there being in this second vessel some sensitive chemical test for faint traces of it; such, for instance, as iron in sulpho- or ferro-cyanide, silver in chloride, copper in ferrocyanide.

Or again, by putting a detecting substance in the tube, the journey of an ion may be continuously watched.

Other things more or less vague might be tried; such as seeing whether there is any difference between applying a high E.M F. to given electrodes in a long narrow vessel, and a small E.M.F. to similar electrodes in a short wide vessel, so that the same current goes through both. One must not expect any variation in the *primary* products of electrolysis probably, but there may be some difference in the secondary effects.

8. *How much of the Current is conveyed by the water and how much by the dissolved salt in any given case?*

To answer this question it seems to me sufficient to determine the amount of free acid generated at either pole, and to compare it with the amount of metal deposited in the same time by the same current.

For instance, with copper sulphate solution and platinum electrodes. If the salt conducted the whole current, one equivalent of free acid would be produced at the anode; if the water conducted the whole, one equivalent of free acid would appear at the cathode; it is easy to see this by drawing the section of a cell and considering its action; and so, by determining the proportion of free acid which actually *does* appear at either pole for given strength of solution and intensity of current, it is easy to reckon how much of the current is by each substance conducted. It is obviously necessary to diminish diffusion between the cathode and anode vessels, and to avoid electric endosmose and the use of porous diaphragms. It is also probably advisable to stir or scrub the surface of both electrodes, so as to avoid a layer of some other liquid forming there, and so confusing the whole reaction.

Migration data, if explained in the way I suggest, will also give a determination of the proportion of current conveyed by salt and by solvent; and it will be interesting to compare the two methods of determination, and see if they give the same result.

If there is a discrepancy, as is very probable, it will be necessary to examine its cause, and to see whether it wholly upsets the suggested migration hypothesis, or only entails some slight modification.

9. *Is any quasi-electrolysis possible across an air-space?*

If there are in acid-water any free dissociated atoms electrically charged, it is just possible, though very unlikely, that they might be pulled out of the liquid by electrostatic attraction.

Thus, if hot acid liquid be one plate of a condenser, the other plate being a hot metal slab half a millimetre above it, and kept at a very different potential, it is just conceivable that the evaporating steam might contain a trace of free hydrogen or free oxygen, according to the sign of the potential of the plate.

10. *Does the energy of Secondary Action contribute to E.M.F. in a cell just as much as the energy of Primary Action, or do secondary actions directly generate heat?*

Dr. Wright distinguishes between what he calls 'adjuvant' and 'non-adjuvant' chemical actions in a cell—those which help the current on, and those which do not.

Lord Rayleigh raised the same question, at the meeting, in considering a Clark cell; for the sulphate of mercury, being nearly insoluble, must certainly be mainly reduced by secondary action if anything like a current is kept going; and yet it seems to contribute to the E.M.F. of the cell.

But one may ask whether the polarisation produced by a moderate current in such a cell is not evidence of the speedy exhaustion of the *dissolved* $HgSO_4$, and of the time taken to replenish the solution from the nearly insoluble paste, thus showing that it is after all the dissolved salt which is really efficient.

Moreover, it seems to me that all reversible effects must contribute to the E.M.F. Helmholtz certainly considers the minor attractions of solvents to be as proportionally effective as the main affinities of ions.

The behaviour of cells which are able to heat or cool themselves, and the variation of their E.M.F. with temperature, are of great interest in the light of the recent theory of Helmholtz. A result deduced from the second law of thermodynamics is pretty surely founded; but experimental verification is always satisfactory, and one can seldom have too much of it.

The laws that want examining are these: Measure the total heat, H, developed per second in cells of various kinds (internal resistance R) by a known current, C; measure also their change of E.M.F. per degree of temperature, dE/dt; then see whether

$$\frac{RC^2 - JH}{C} = (274 + t)\ \frac{dE}{dt}.$$

Further examine whether each of these quantities is also equal to the difference between the observed E.M.F. of the cell and that calculated from purely chemical data, viz. to $E - \Sigma\ (J\epsilon\theta)$.

11. *Is specific inductivity a constant, or does it tend towards zero for very high strains in the same sort of way that magnetic permeability does?*

I am not aware that the capacity of a highly-charged condenser has ever been seriously measured. It seems a desirable but difficult thing to do.

12. *How does dielectric strength depend upon density?*

Considerable work has been done in measuring the dielectric strength of different gases at various pressures, but we cannot be said to know the law even for air; nor is the truth about the great strength of approximate vacua on the one hand, and very high pressure gas on the other, at all certain. The dielectric strength of insulating liquids ought also to be measured; and it might be tried how far pressure affects them.

The effect of pressure upon electrolysis has been worked at, and may be said to be fairly understood. The effect of pressure on disruptive discharge, and the internal pseudo-conductivity of gases after elimination of discontinuities such as cathode-resistance, is more obscure.

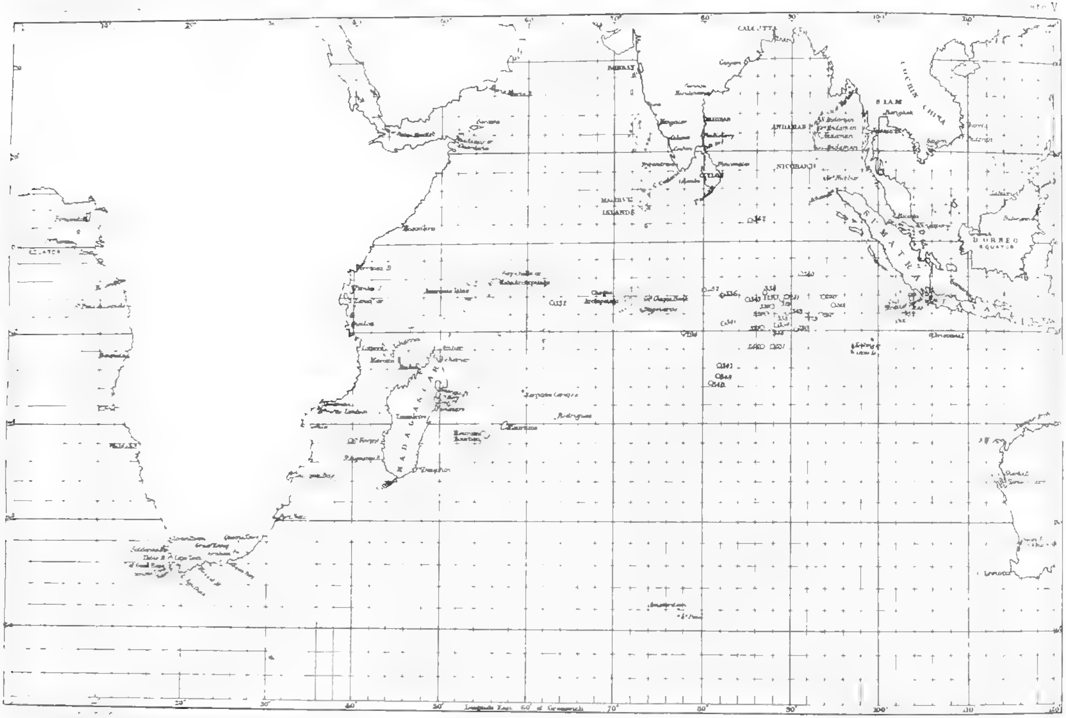
FROM AUG TO DEC 1883 — THE PLACE OF OBSERVATION IS SHOWN THUS ○, THE DATE IS GIVEN BY THE DAY OF THE YEAR THUS ○300 27TH OCT



Illustrating Mr Meldrum's Tabular Statement of the Dates at which and Localities where Pumice or Volcanic Dust was seen in the Indian Ocean in 1883-84

A Tabular Statement of the Dates at which, and the Localities where, Pumice or Volcanic Dust was seen in the Indian Ocean in 1883–84. *By* CHARLES MELDRUM, *F.R.S.*

[PLATES V. and VA.]

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

Names of Vessels	Month and Day	Hours	Position at Noon		Remarks
			Lat.	Long.	
	1883			E.	
Barque *Actæa* (Capt. Walker)	May 20	2 p.m. to	6° 50′ S.	101° 02′	Very fine dust commenced to fall about 2 p.m. The fall continued all night, and stopped about 9 a.m. on the 21st. Small quantities fell again during the night.
	,, 21	9 a.m.			
	,, 21	night			
Ship *Idomene* (Capt. Johnson)	Aug. 11	8 a.m. to 2 p.m.	6 23 S.	88 31	Passed through large fields of pumice.
Barque *West Australian* (Capt. Thomas)	,, 17	noon	8 35 S.	91 53	Passed a great amount of floating lava or pumice.
	,, 18	noon	9 41 S.	90 28	Passed a great amount of lava to-day.
	,, 19	noon	11 08 S.	88 03	Large quantities of pumice; some pieces about 3 feet in diameter.
S.S. *Anerly* (Capt. Strachan)	,, 27	—	North Watcher		Ashes began to fall at 10.24 a.m. Showers of ashes and pumice lasted till midnight.
	,, 28	—	Auger Roads		Immense quantities of pumice and débris of all sorts.
Barque *County of Flint* (Capt. J. Rowland)	,, 28	noon	8 20 S.	92 04	Great quantity of dust falling; supposed to be coral dust.
French brig *Brani* (Capt. E. Perrot)	,, 28	5 a.m.	4 22 S.	89 14 E. P.	L'atmosphère surchargé de sable. De minuit à 11 heures du matin une très grande quantité de sable très blanc et très fin a couvert toutes les parties accessibles, même presque dans la chambre. Je crois que c'est le résultat d'un orage que nous avions observé ces jours derniers sur Sumatra, pendant lequel le tonnerre avait des roulements

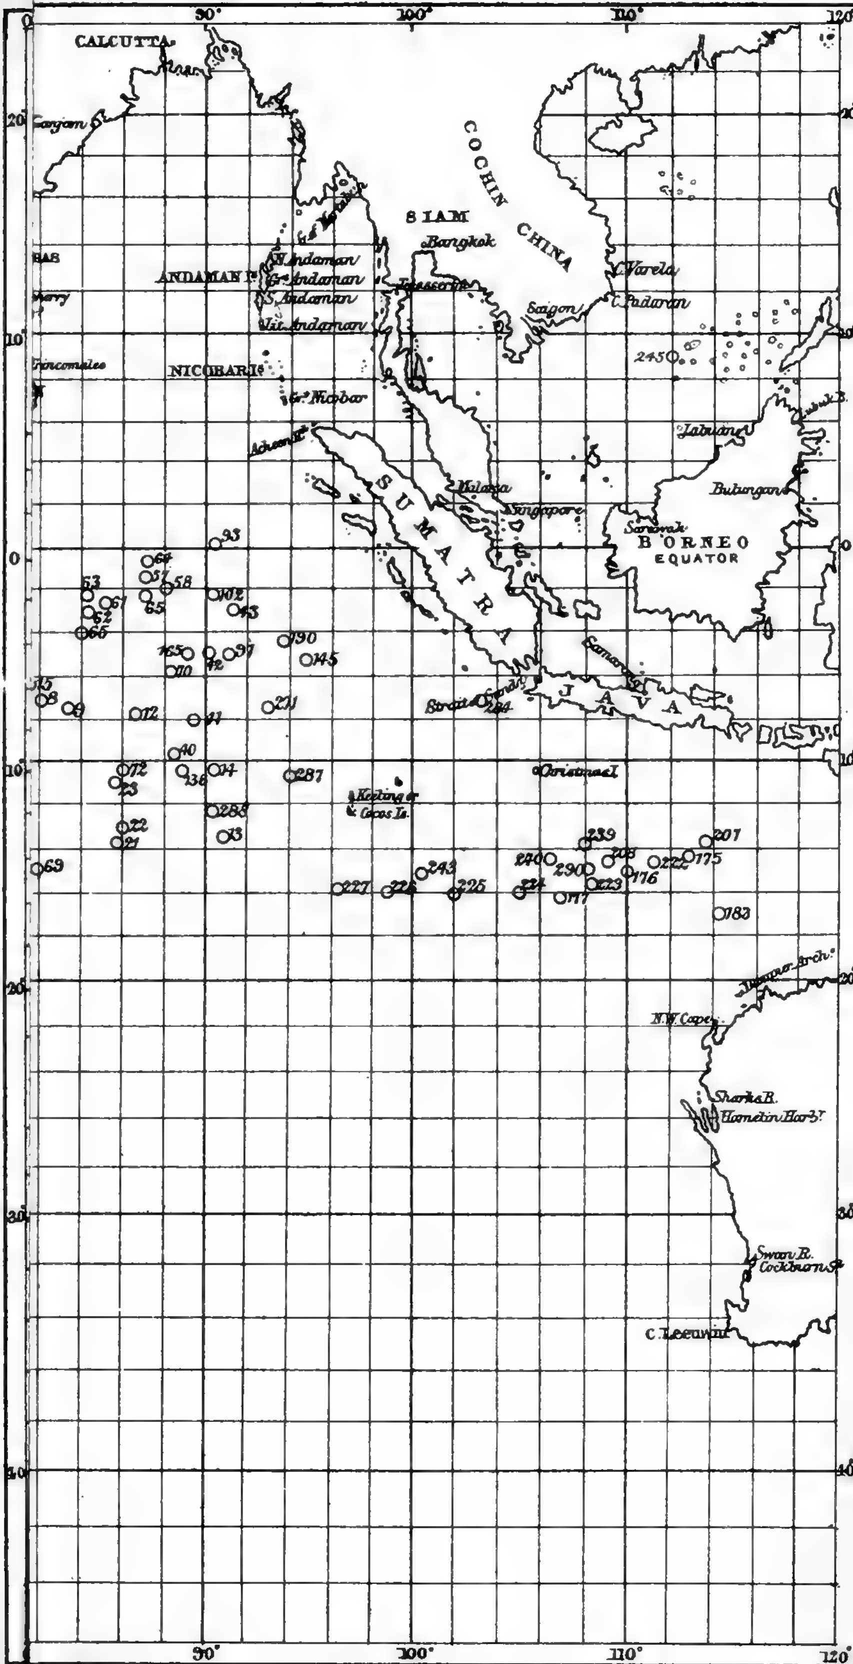
Names of Vessels	Month and Day	Hours	Position at Noon		Remarks
			Lat.	Long.	
	1883		° ′	E. ° ′	
French brig *Brani*—cont.					pareils à une canonnade, et le sable enlevé par cette tourmente a été renvoyé sur nous par la petite brise.
	Aug. 29	9 a.m.	5 50 S.	89 00 E. P.	Il tombe continuellement du sable très fin au point d'obscurcir l'atmosphère.
Barque *Castleton* (Capt. Dioré)	„ 28	2 a.m.	5 58 S.	93 30	After a shower of rain the air became loaded with a fine dust, which fell in great quantities on deck. At noon dust still falling. At 2 p.m. dust still falling.
	„ 29	6 a.m. 2 p.m.	6 56 S.	93 01	Collected dust off the deck. Pumice-stone floating in the water. At 2 p.m. dust still falling: large quantities of pumice floating past.
Brigantine *Airlie* (Capt. Knight)	Sept. 9	6 a.m. 2 p.m.	7 31 S.	103 11	Large quantities of lava. Passing through large quantities of lava.
French barque *Gipsy* (Capt. Martin)	„ 9	9 a.m.	4 57 S.	79 46 E. P.	Grand banc flottant de pierre-ponce pendant toute la journée, suivant le vent comme dans la mer de Sargosse.
French barque *Marie Alfred* (Capt. Brégeon)	„ 20	6 a.m.	7 02 S.	101 15	Nous passons dans des bancs successifs et très rapprochés de pierre-ponce.
Barque *Hottenburn* (Capt. Chichester)	Oct. 13	4 p.m.	Sunda Straits		Tremendous fields of pumice stopped the vessel.
	„ 14	4 a.m.	No obs.		Lots of pumice alongside.
	„ 15	midt.	7 19 S.	104 00	Passing large fields of pumice.
S.S. *Garonne*	„ 21	9·15 a.m.	10 15 S.	78 07	Passed through several fields of pumice-stone of various sizes. Some pieces that were picked up had barnacles nearly one inch long adhering to them.
S.S. *Countess of Errol* (Capt. Taylor)	„ 26	noon	7 01 S.	104 49	Vast quantities of pumice all round the ship.

Names of Vessels	Month and Day	Hours	Position at Noon		Remarks
			Lat.	Long.	
	1883			E.	
S.S. *Countess of Errol* —cont.	Oct. 27	8 a.m.	8° 44′ S.	102° 40′	Sailing through vast quantities of pumice.
Barque *Rollo* (Capt. Currie)	Nov. 15	6 a.m.	6 19 S.	88 55	Since daylight sailing through large quantities of pumice. At midnight still large quantities of pumice floating on water.
	,, 16	noon	8 04 S.	87 25	Still large quantities of pumice floating past.
	,, 17	noon	9 36 S.	85 46	,, ,, ,,
Barque *Eva Joshua*) (Capt. Florentin)	,, 28	8 a.m.	6 24 S.	62 25 E. P.	Sailing all day through floating pumice covered with barnacles.
French barque *Henriette* (Capt. A. de Lavit)	Dec. 2	5 a.m.	5 42 S.	86 47 E. P.	Au jour nous avons remarqué que nous étions environné de pierre-ponce. A 9 heures nous sommes toujours entouré de pierre-ponce.
	,, 3	5 a.m.	No obs.		Il y a encore de pierre-ponce.
	,, 4	6 a.m.	7 14 S.	87 32	Nous avons encore rencontré de pierre-ponce.
	,, 5	9 a.m.	8 44 S.	?	Nous recontrons encore beaucoup de pierre-ponce.
Barque *Ta Lee* (Capt. Stolzee)	,, 2	4 p.m.	6 07 S.	81 55	Passed a bank of pumice extending about twenty-five miles; some pieces about two feet square.
	,, 7	a.m.	8 59 S.	82 14	Still passing pumice-stone and a kind of ashes.
Ship *Shah Jehan* (Capt. Williams)	,, 9	6 a.m.	7 26 S.	84 58	Noticed the sea covered in streaks with what appeared to be pumice-stone in pieces and in powder; lowered the boat and picked up some; some of the stones covered with barnacles.
	,, 13	—	13 47 S.	82 00	Throughout the day the sea covered in streaks with some kind of lava and large-sized lumps of pumice-stone.
	,, 14	—	15 03 S.	81 42	Passed a great deal of pumice and lava this day.

Names of Vessels	Month and Day		Hours	Position at Noon		Remarks
				Lat.	Long.	
	1883				E.	
Ship *Shah Jehan*—cont.	Dec.	15	—	15° 30′ S.	80° 51′	Passed a lot of pumice and lava.
Ship *Invercauld* (Capt. Leslie)	"	12	8 a.m.	11 45 S.	87 09	Passed through a quantity of dust seemingly floating on the surface.
	"	14	10 a.m.	9 54 S.	87 56	Passed through a quantity of pumice-stone.
	"	15	a.m.	7 56 S.	89 32	Passed large quantities of pumice-stone.
Barque *Evelyn* (Capt. Stevenson)	"	20	noon	9 40 S.	88 11	Passing great quantities of pumice.
	"	21	?	7 30 S.	88 26	Still passing quantities of pumice.
Barque *May Queen* (Capt. Hugon)	"	28	—	2 14 N.	85 35	Une infinité de parcelles de roche brûlée sur l'eau.
	1884					
Sch. *Lord Tredegar* (Capt. Clarke)	Jan.	5	2 p.m.	6 35 S.	68 25	Passed through a quantity of lava.
	"	8	noon	12 12 S.	66 59	" " "
	"	9	—	14 56 S.	65 18	Passed through a great quantity of pumice to-day.
	"	10	noon	17 34 S.	63 04	" " "
French barque *Résolu* (Capt. Mouton)	"	8	p.m.	7 05 S.	81 41 E. P.	Traversé plusieurs bancs de pierre-ponce.
Barque *May Queen* (Capt. Hugon)	"	9	a.m.	7 00 S.	83 13	Une infinité de roche brûlée flottant.
	"	12	p.m.	11 23 S.	75 46	Une infinité de débris volcaniques.
Ship *Argomene* (Capt. H. Williams)	"	12	8 p.m.	7 51 S.	87 05	Passing through large quantities of pumice.
Ship *Roderick Dhu* (Capt. Boldchild)	"	13	4 p.m.	13 34 S.	90 50	Passing through large quantities of pumice.
	"	14	p.m.	9 25 S.	90 26	" " "
French barque *Eugénie* (Capt. A. Arnaud)	"	15	p.m.	6 14 S.	81 40	Beaucoup de pierre-ponce formant de lis allongé à l'ouest.
Barque *Star of Greece* (Capt. W. Legg)	"	21	7 a.m.	13 49 S.	85 45	Large quantities of pumice in separate streams from S.E. to N.W. At 6 p.m. still passing large quantities of pumice.
	"	22	2 a.m.	13 21 S.	86 06	The streams of pumice-stone stopped.
	"	23	midt.	10 45 S.	85 50	A large stream of pumice-stone.
Barque *Era Joshua* (Capt. Florentin)	"	22	p.m.	13 05 S.	64 20 E. P.	Sighted pumice-stone.
Sch. *Glenesk* (Capt. Feleng)	"	26	a.m.	3 19 S.	78 45 E. P.	Rencontré à chaque instant des bancs formés par des pierres-ponce.
Sch. *Mary Whitridge* (Capt. Howes)	Feb.	9	7 a.m.	9 41 S.	88 26	Passing lots of floating pumice-stone.

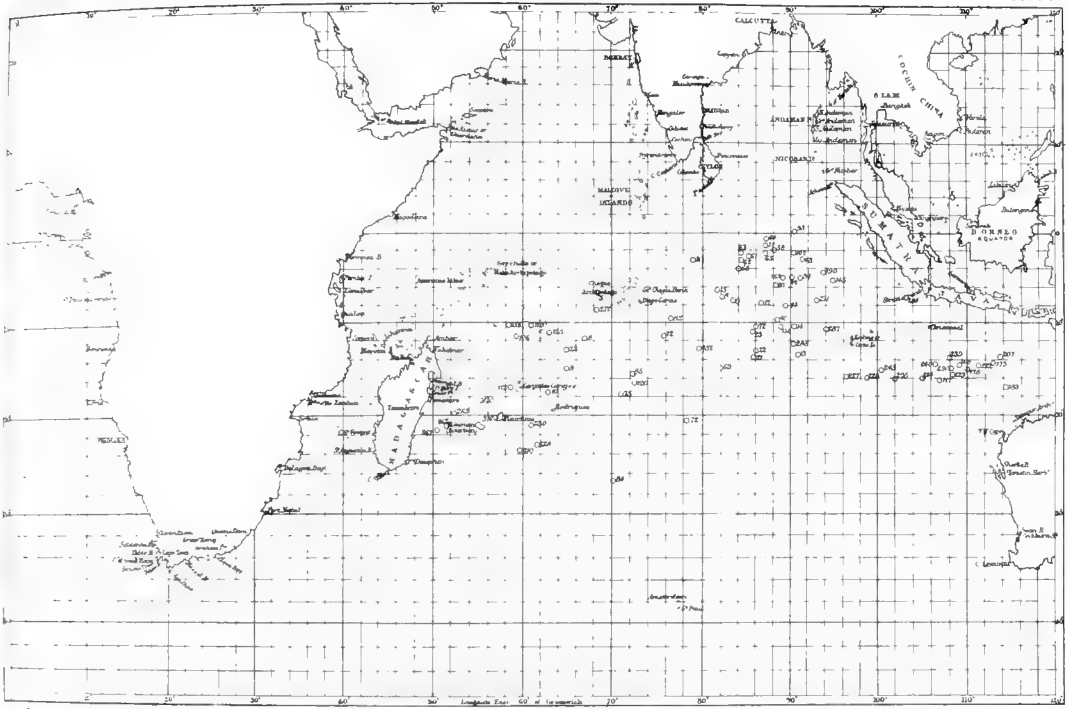
SEEN IN THE INDIAN OCEAN

Plate Va



c Dust was seen in the Indian Ocean in 1883-84.

CHART SHOWING WHERE AND WHEN PUMICE OR VOLCANIC DUST WAS SEEN IN THE INDIAN OCEAN FROM JAN. 1884 TO NOVEMBER 1884.



Illustrating Mr Meldrum's Tabular Statement of the Dates at which, and Localities where, Pumice or Volcanic Dust was seen in the Indian Ocean in 1883-84.

Sch. *Iris* (Capt. Shaw)	July 1	2 a.m.	17 08 S.	114 33	Passing vast quantities of pumice.
Ship *Reigate* (Capt. Ritchie)	„ 8	7 a.m.	4 25 S.	93 47	Passed through large quantities of pumice.
Barque *Northern Star* (Capt. Evans)	„ 25	4 a.m.	13 42 S.	113 42	Large quantities of pumice floating on the water.
	„ 26	4 a.m.	14 46 S.	109 43	„ „ „
Sch. *Catherine Marie* (Capt. Stubington)	„ 28	7 a.m.	23 36 S.	59 40	Passed through quantities of pumice varying in size from an orange to a walnut shell. Picked up some pieces covered with barnacles and limpets.
Barque *City of Tanjore* (Capt. Sinclair)	Aug. 9	4 p.m.	14 45 S.	111 20	Passed small pieces of pumice.
	„ 10	noon	15 28 S.	108 12	Sailing through large quantities of pumice floating in streaks like Gulf-weed.

Names of Vessels	Month and Day		Hours	Position at Noon		Remarks
				Lat.	Long.	
	1884				E.	
Barque *City of Tanjore*—cont.	Aug.	11	5 a.m.	16° 05′ S.	104° 53′	Still sailing through quantities of pumice. Passed a large spar in the water.
	„	12	8 a.m.	16 00 S.	101 56	Still sailing through pumice.
	„	13	4 p.m.	16 04 S.	99 05	„ „ „
	„	14	4 p.m.	16 06 S.	96 16	Less pumice to-day.
Sch. *Jasper* (Capt. Stannard)	„	15	a.m.	23 06 S.	61 47	Passed several pieces of floating pumice.
	„	17	a.m.	20 56 S.	61 01	„ „ „
Barque *Marion Neil* (Capt. Paterson)	„	26	8 a.m.	14 09 S.	108 06	A lot of pumice-stone floating past.
	„	27	6 a.m.	14 36 S.	106 39	„ „ „
	„	30	8 a.m.	15 19 S.	100 30	„ „ „
Barque *Jane Maria* (Capt. Griffiths)	Sept.	1	7.30 a.m. to noon	9 10 N.	112 11	Passed through a quantity of very small pumice-stone.
Sch. *Coleridge* (Capt. Marshall)	„	17	noon	21 15 S.	50 20	Several pieces of floating pumice.
	„	18	4 p.m.	20 39 S.	51 10	Passed large quantities of pumice which, apparently has been a long time in the water.
	„	19	noon	20 04 S.	52 24	„ „ „
Barque *Caller Ou* (Capt. Rae)	„	27	8 a.m.	7 20 S.	93 02	Much lava floating about.
S.S. *Castlebank* (Capt. Chevalier)	„	28	3 p.m.	8 39 S.	68 31	Passed through large quantities of pumice, which seems to have been a long time in the water.
Barque *Jane Maria* (Capt. Griffiths)	Oct.	10	p.m.	6 58 S.	102 54	Passed a large quantity of floating pumice.
	„	13	3.30 p.m.	10 44 S.	93 57	Passed a large quantity of very small pumice.
	„	14	5 a.m.	12 33 S.	90 19	„ „ „
	„	14	5 p.m.	—	—	Large and small pieces of pumice seen frequently during the afternoon.
French barque *France Chérie* (Capt. Lavary)	„	16	—	15 09 S.	107 39 E. P.	Depuis plusieurs jours la mer est couverte de pierre-ponce.
	Nov.	11	—	20 21 S.	56 35 E. P.	J'ai parcouru environ une étendue de 1,200 milles par latitude sud où j'ai rencontré beaucoup de pierre-ponce.

List of Works on the Geology, Mineralogy, and Palæontology of Staffordshire, Worcestershire, and Warwickshire.

By WILLIAM WHITAKER, *B.A., F.G.S., Assoc.Inst.C.E.*

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

2. STAFFORDSHIRE.

Geological Survey Publications.

Maps. Scale an inch to a mile.

(1) Sheet 54, N.W. (small part at N.). By A. C. Ramsay, J. B. Jukes, H. H. Howell, and E. Hull, 1852. New Ed. 1855.

(2) Sheet 55, N.E. (small part at N.E.) By J. Phillips, W. T. Aveline, and H. H. Howell. 1853. New Ed. 1855.

(3) Sheet 61, S.E. (E. edge). By W. T. Aveline and E. Hull, 1852. New Ed. 1855.

(4) Sheet 61, N.E. (N.E. corner and a little at S.E.). By W. T. Aveline, E. Hull, and A. C. Ramsay. ? no date. Reissued 1855.

(5) Sheet 62, S.W. (all but S. and S.E. parts.—Bilston, Dudley, Walsall, Wednesbury, Wolverhampton). By A. C. Ramsay, J. B. Jukes, and E. Hull. 1852. New Eds. in 1855 and 1858.

(6) Sheet 62, S.E. (at N.W. and S.W.—Birmingham). By A. C. Ramsay and H. H. Howell. 1855 ? New Ed. in 1868.

(7) Sheet 62, N.W. (Brewood, Cannock, Penkridge, and Rugeley). By J. B. Jukes, E. Hull, and H. H. Howell. 1852. New Eds. 1855, 1858, 1859, partly by A. C. Ramsay.

(8) Sheet 62, N.E. (all but N.E. and S.E. corners. Tamworth and Litchfield). By A. C. Ramsay and H. H. Howell. 1856. New Ed. 1868.

(9) Sheet 63, N.W. (very small piece on W.). By H. H. Howell and E. Hull, 1855.

(10) Sheet 71, S.W. (very small piece on W.). By E. Hull, 1855.

(11) Sheet 72, S.W. (Stafford, Stone). By E. Hull, 1852. New Ed. 1855.

(12) Sheet 72, S.E. (all but N.E. part and S.E. corner.—Abbot's Bromley, Burton, Uttoxeter). By H. H. Howell, 1852.

(13) Sheet 72, N.W. (Cheadle, Hanley, Newcastle, Stoke). By W. W. Smyth and E. Hull. 1857. Additional information, by A. H. Green, 1868.

(14) Sheet 72, N.E. (W. part). By J. Phillips, A. C. Ramsay, and E. Hull. 1852. New Ed. 1855. Additions, by A. H. Green, 1878.

(15) Sheet 73, S.E. (E. part.—Eccleshall). By A. R. Selwyn and E. Hull. 1855.

(16) Sheet 73, N.E. (at E. and S.E.). By W. W. Smyth and E. Hull. 1857.

(17) Sheet 81, S.W. (S.E. part.—Leek). By A. H. GREEN, 1864.

(18) Sheet 81, S.E. (S.W. corner. Longnor). By J. PHILLIPS and W. W. SMYTH, 1852. Revisions, by A. H. GREEN and J. R. DAKYNS, 1866.

Horizontal Sections. Scale six inches to a mile.

(19) Sheet 18 (top line). Section from the Red Marl plain of Cheshire across the Lower Carboniferous rocks of North Staffordshire. . . . By J. PHILLIPS and A. H. GREEN. New edition, 1866. (Ed. 1 does not refer to Staffordshire.)

(20) Sheet 23. South Staffordshire. Section No. 1, North and South, from Bellbroughton, through the Clent Hills, Dudley, Bentley, Norton, Beaudesert, and Brereton, to the neighbourhood of Rugeley. No. 4 . . . across the extreme northern end of the S. Staffordshire coal-field. No. 5 . . . from Wyrley to Pelsall. By J. B. JUKES. 1853. Revised 1865.

(21) Sheet 24. South Staffordshire. Section No. 2 . . . from Lappal, by Rowley, Dudley, and Sedgley, to Compton. . . . No. 3, North and South, through Hagley Park, Brickley Hill, Barrow Hill, Turners Hill and Lidget Hill. No. 6, East and West. Through Sedgley, Darlaston and Walsall to Barr Beacon. By J. B. JUKES. ? date. Additions and corrections, by A. C. RAMSAY, H. H. HOWELL, and E. HULL, 1856. Revised 1865.

(22) Sheet 25. South Staffordshire. Section No. 7, East and West through Kingswinford, Dudley, and Westbromwich. No. 8, East and West through Wordesley, Brierley Hill, Rowley, and Langley. No. 9 East and West from Stourbridge by Cradley, the Hawn, Mucklowhill and the Quinton. No. 10, North and South, Through Frankley Beeches, Hasbury, Hawn, . . . to the Old Lion Colliery. By J. B. JUKES, 1853. Additions, by A. C. RAMSAY, H. H. HOWELL, and E. HULL, 1856. Revised 1865.

(23) Sheet 41. Section from South West to North East across . . . New Red Sandstone, Permian, the North Staffordshire Coalfield and Carboniferous Limestone, through Norton, Whitmore Heath, Longton to Waterfall Low. By E. HULL and A. H. GREEN, 1857.

(24) Sheet 42. Section from West to East across the New Red Sandstone; the North Staffordshire Coalfield . . . through Talk, Endon & Parwich. By E. HULL and A. H. GREEN, 1857. Revisions 1868.

(25) Sheet 45. No. 1. Section from West to East across the . . . New Red Sandstone, near . . . Wrottesley Park, and Bushbury, & the S. Staffordshire Coalfield, by Essington Wood, and Pelsall Wood, to the Lichfield Road. By E. HULL. 1858.

(26) Sheet 49. Section 1. From Barr Beacon . . . (small piece only). By H. H. HOWELL, 1858.

(27) Sheet 54. No. 1. Section from N.W. to S.E. . . . to Baggeridge Wood, S. of Wolverhampton, Staffordshire. No. 2. Section from West to East . . . to Oreton Hill, South Staffordshire, through the . . . New Red Sandstone. By E. HULL. 1858.

(28) Sheet 57. No. 1. Section from S.W. to N.E. across the New Red Sandstone and Permian Rocks, N. of Stone, Fulford & Drayeott, the Coalfield of Cheadle, to the Carboniferous Limestone of Throwley Low, North Staffordshire. No. 2. Section from S. to N. across the New Red Sandstone of Rugeley, North Staffordshire, the New Red Marl and

Lias, of Bagot Park; to the Carboniferous Limestone of the Weaver Hills. By E. HULL and A. H. GREEN. 1859.

(29) Sheet 58. Section No. 2. From West to East . . . across . . . the Permian Rocks and New Red Sandstone, near Shiffnal and Brewood, to the Western border of the S. Staffordshire Coal-field, S. of Cannock. By E. HULL and H. BAUERMAN. 1860.

Vertical Sections. Scale 40 feet to an inch.

(30–32) Sheets 16–18. Vertical Sections in the South Staffordshire Coal-field. By J. B. JUKES, 1853.

(33) Sheet 26. Pit Sections from the South Staffordshire Coal Field. By J. B. JUKES, 1860.

Memoirs, 8vo, London.

(34) On the Geology of the South Staffordshire Coalfield. By J. B. JUKES. Records of the School of Mines, Part ii. Pp. 149–348 (1853) Ed. 2, as a separate Memoir, 'The South Staffordshire Coal-field,' Pp. xiv, 241 (1859).

(35) The Triassic and Permian Rocks of the Midland Counties of England. By E. HULL. Pp. x, 127 (1869).

(36) The Iron Ores of Great Britain. Part ii. The Iron Ores of South Staffordshire. By J. B. JUKES, J. SPILLER, A. DICK, and C. TOOKEY. Pp. iv, 99–164 (1858).

(37) Do: Part IV. Iron Ores of . . . North Staffordshire. Pp. 255–296. By W. W. SMYTH, A. DICK, J. SPILLER, and J. W. SALTER (Notes on the Fossils). (1862).

BOOKS, PAPERS, ETC., CHRONOLOGICALLY ARRANGED

To the end of 1873, after which year the GEOLOGICAL RECORD gives an account of works on English Geology.

1679 and 1686.

(38) PLOTT, DR. R. Natural History of Staffordshire. Fol. *Oxon.*

1683.

(39) PLOTT, DR. R. The Contents of some Letters from Two learned and curious Observers in Staffordshire, concerning the Sand found in the Brine of the Saltworks of that Country. *Phil. Trans.* vol. xiii. no. 145, p. 96.

1684.

(40) LISTER, DR. M. Certain Observations of the Midland Salt-Springs of Worcester-shire, Stafford-shire, and Cheshire. *Phil. Trans.* vol. xiv. No. 156, p. 489.

1712?

(41) BELLERS, F. A Description of the several Strata of Earth, Stone, Coal, &c., found in a Coal-Pit at the West End of Dudley in Staffordshire. To which is added a Table of the Specifick Gravity of each Stratum. *Phil. Trans.* vol. xxvii. No. 336, p. 541.

1740.

(42) SHORT, DR. T. An Essay Towards A Natural, Experimental, and Medicinal History of the Principle Mineral Waters of . . . Staffordshire, Warwickshire, Worcestershire, &c. 4to. *Sheffield.*

1751.

(43) LYTTELTON, REV. DR. C. A Letter concerning a nondescript petrified Insect. [Dudley]. *Phil. Trans.* vol. xlvi. no. 496, p. 598. With 'Some farther Account of the before-mentioned Dudley Fossil,' by the Editor (Dr. C. MORTIMER), p. 600.

1773.

(44) WITHERING, DR. W. Experiments upon the different Kinds of Marle found in Staffordshire. *Phil. Trans.* vol. lxiii. part 1, p. 161.

1774.

GEOLOGICAL SURVEY PUBLICATIONS.

Nos. 1, 2, 3, 5, 6, 20, 22, 34, 35 of the Staffordshire List refer also to Worcestershire.

Maps. Scale an inch to a mile.

(254) Sheet 43, N.E. (N.E. part.) By [PROF.] J. PHILLIPS and H. H. HOWELL, 1845. New edition, 1855.

(255) Sheet 44. (N.W. part. Evesham, Upton.) By H. H. HOWELL and [PROF.] E. HULL, 1856.

(256) Sheet 54, S.W. (Droitwich, Pershore, Worcester.) By H. H. HOWELL, 1854.

(257) Sheet 54, S.E. (S. part.) By H. H. HOWELL, 1854.

(258) Sheet 54, N.W. (Bromsgrove, Droitwich). By [SIR] A. C. RAMSAY, [PROF.] J. B. JUKES, H. H. HOWELL, and [PROF.] E. HULL. 1852. New Ed. 1855.

(259) Sheet 54, N.E. (N.W. Part.) By H. H. HOWELL. 1855.

(260) Sheet 55, S.W. (little bit at N.E. corner.) By W. T. AVELINE and A. R. SELWYN. 1850.

(261) Sheet 55, S.E. (E. half.) By [PROF.] J. PHILLIPS, W. T. AVELINE, A. R. SELWYN, and H. H. HOWELL. 1853. New Ed. 1855.

(262) Sheet 55, N.W. (little bit at S.E. corner. Tenbury). By W. T. AVELINE. 1850 and 1855.

(263) Sheet 55, N.E. (Bewdley, Kidderminster, Stourport.) By [PROF.] J. PHILLIPS, W. T. AVELINE, and H. H. HOWELL, 1853. New Ed. 1855.

Horizontal Sections. Scale 6 inches to a mile.

(264) Sheet 13. (3. Berrow Hill; 4. N. point of Swinyard Hill; 5. Herefordshire Beacon; 6. The Wych.) By [SIR] A. C. RAMSAY and [PROF.] J. PHILLIPS.

(265) Sheet 50. (Section from Neen Soller, near Cleobury Mortimer.) Worcestershire across the Forest of Wyre Coalfield, through the intervening Permian and New Red Sandstone strata. . . . By H. H. HOWELL, 1858.

(266) Sheet 59. By [PROF.] E. HULL. 1860.

Vertical Section. Scale 40 feet to an inch.

(267) Sheet 15. Section from the Old Red Sandstone through the Silurian Strata, to the Syenitic Rocks of the Malvern Hills. By PROF. J. PHILLIPS.

Memoirs. 8vo. London.

(268) The Malvern Hills, compared with the Palæozoic Districts of Abberley. . . . By [PROF.] J. PHILLIPS. With Palæontological Appendix, by J. PHILLIPS and J. W. SALTER. Vol. ii. pt. i. 1848.

(269) The Geology of the Country around Cheltenham. (Sheet 44.) By [PROF.] E. HULL. 1857.

(270) Explanation of Horizontal Sections. (Sheets 50 & 51.) 1859.

(271) Description of Horizontal Section, Sheet 59. By [PROF.] E. HULL. 1861.

BOOKS, PAPERS, ETC., CHRONOLOGICALLY ARRANGED.

Nos. 40, 42, 57, 70, 72, 80, 112, 121, 126, 134, 135, 137, 143, 156, 174, 175, 188, 189, 195, 205, 212, 219, 233, 235 of the Staffordshire List refer also to Worcestershire.

4. WARWICKSHIRE.

A Warwickshire List was published in *Rep. Rugby School Nat. Hist. Soc.* for 1872, pp. 66–76; but it may fairly be reproduced here (rearranged and with a few additions), in order to complete the geologic bibliography of the district around Birmingham.

GEOLOGICAL SURVEY PUBLICATIONS.

Nos. 5, 6, 9, 26, 255, 256, 257, 259, 265 of the Staffordshire and Worcestershire Lists refer also to Warwickshire.

Maps. Scale an inch to a mile.

(401) Sheet 45, N.W. (N.W. corner). By H. BAUERMAN and T. R. POLWHELE. 1859.

(402) Sheet 53, S.W. (Kington, Southam.) By H. H. Howell. 1856.

(403) Sheet 53, N.W. (Coventry, Rugby, Warwick.) By [Sir] A. C. Ramsay and H. H. Howell. 1854.

(404) Sheet 53, N.E. (W. edge, Rugby.) By H. H. Howell. 1859.

(405) Sheet 63, S.W. (Atherstone, Nuneaton.) By H. H. Howell. 1854.

(406) Sheet 63, S.E. (small piece at S.W. corner). By [Sir] A. C. Ramsay and H. H. Howell. 1854.

Horizontal Sections. Scale 6 inches to a mile.

(407) Sheet 48. (From Lazy Hill, across the Warwickshire Coal-field to Wysall.) By H. H. Howell. 1856.

(408) Sheet 51 (part). Section through . . . the Warwickshire Coal Field, &c. By H. H. Howell. 1858.

Vertical Section. Scale 40 feet to an inch.

(409) Sheet 21. Warwickshire Coalfield. By H. H. Howell. 1857.

Memoir, 8vo. *London.*

(410) The Geology of the Warwickshire Coal-field and the Permian Rocks and Trias of the Surrounding District. By H. H. Howell. 1859.

Books, Papers, etc., chronologically arranged.

Nos. 42, 54, 57, 65, 66, 67, 72, 74, 75, 85, 90, 124, 134, 137, 143, 172, 241, 282, 283, 288, 309, 311, 313, 316, 317, 322, 342, 343, 354, 359, 361, 369, 378, 384, 386, 389, 392 of the Staffordshire and Worcestershire Lists refer also to Warwickshire.

On Slaty Cleavage and Allied Rock-Structures, with special reference to the Mechanical Theories of their Origin. By Alfred Harker, *M.A., F.G.S.*

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

I. *Introductory and Historical.*

The following paper is intended to deal in a comprehensive, though far from exhaustive, manner with the main phenomena of the cleavage structure in slate-rock, the received views of the origin and significance of these phenomena, and the relations existing between slaty cleavage and various allied rock-structures. It may be regarded as to some extent supplementary to the Report on Cleavage and Foliation presented to the British Association at the Cheltenham meeting in 1856 by the late Professor John Phillips;[1] and accordingly a few words seem to be called for in justification.

The facts so ably summarised by Professor Phillips were much less complete than those now at our disposal, and although they were perhaps sufficient in 1856 to establish on a firm basis the mechanical theories of slaty cleavage which had been already put forward by Messrs. Sharpe and Sorby, it could not be said that such theories had obtained anything like universal acceptance. Indeed Professor Phillips had in contemplation[2] a further report, in which the 'mechanical pressure' which these authors advocate' was to be 'placed in comparison with the crystalline polarity, formerly advanced by Professor Sedgwick,' and in which 'Mr. Fox's ingenious imitation of slaty cleavage by electrical currents' was also to receive attention. Following the tendency of more recent speculations, I propose to discuss the subject of slaty cleavage from a purely mechanical standpoint. Such an investigation will involve considering the relations of cleavage to contortion, to faulting, to jointing, and to foliation, subjects which had received but little notice at the date of Professor Phillips' report, but some of which are now recognised as among the foremost questions of geology.

Slaty cleavage may be defined as a superinduced tendency in a rock to split in a definite direction more readily than in other directions, such direction of splitting being independent of the planes of deposition in a sedimentary rock. In the classical paper of Professor Sedgwick,[3] referred to below, the following passage occurs: 'Besides the planes of cleavage, we may often find in large slate quarries one or more sets of cross joints, which, combined with the cleavage, divide the rock into rhombohedral solids. Should any one assert that this subdivision of slate rocks into rhombohedral solids implies three planes of cleavage, we might reply,

[1] *British Association Report*, 1856, p. 369. 'Report on Cleavage and Foliation in Rocks, and on the Theoretical Explanations of these Phenomena. Part I.'

[2] *Op. cit.*, p. 392.

[3] *Geol. Trans.*, 2nd ser., vol. iii. p. 473, 1835.

that such solids are not capable of *indefinite* subdivision into similar solids, except in one direction, viz., that of true cleavage.' The distinction here stated between true slaty cleavage and mere jointing is fundamental: slaty cleavage, like the crystalline cleavage of minerals, is a property of a definite *direction*, jointing a property of definite planes in the rock. If a rock-mass will split along a certain plane owing to a true slaty cleavage structure, it will split with equal readiness along any other plane parallel to the first; but although parallel joints may occur in a rock at very small distances apart, there is no special tendency in the parts of the rock between two successive joints to split parallel to them. Moreover, cleavage planes are merely surfaces of weakness, not of actual discontinuity, in the rock in which they occur; while, although secret or 'close' joints are not uncommon in some kinds of rocks, the structural planes properly known as joints are usually actual fissures, which may, however, be of very minute width.

The structure of slaty cleavage, to which the above remarks are strictly applicable, is typically exemplified in ordinary roofing-slate: in some other rocks we find a passage from the true cleavage structure to a system of close parallel planes of discontinuity (which, however, are not to be with propriety regarded as joints), while, on the other hand, it is difficult to discriminate the cleavage of slates from the *schistosité* of certain schists.

The words *clivage* and *Transversalschieferung*, when strictly appropriated,[1] are used in nearly the same sense as that in which we have defined cleavage: the first-named term is, however, employed by many writers with reference to structures which we should describe as jointing.

It seems desirable, if possible, to limit the name *slate* to rocks which exhibit the true cleavage-structure, although this restriction has not always been observed.

Confining our attention for the present to true slaty cleavage, it will be convenient to summarise at the outset the information that had been obtained on that subject prior to Professor Phillips' Report in 1856.

It is a matter of no small wonder that the fundamental difference of cleavage planes from surfaces of original deposition should have met with such tardy recognition at the hands of geologists in general. In North Wales, for instance, where some of the quarries have been worked for at least six centuries,[2] the cleavage-planes are often seen to cut at high angles across alternating bands of different lithological characters, which clearly indicate the original bedding of the rocks. The names of Otley,[3] MacCulloch,[4] and Phillips may be mentioned as among the first to recognise slaty cleavage as a distinct phenomenon. The scientific study of the structure must, however, be considered as dating from Prof. Sedgwick's paper 'On the Structure of Large Mineral Masses,'[5] read before the Geological Society of London in 1835. In this valuable contribution to physical geology the author insisted anew upon the distinction between cleavage and stratification, and pointed out clearly for the first time how the former structure differs from jointing; he showed that cleavage-planes

may cut the bedding at any angle, according to the varying dips and contortions of the latter; he stated that they are much more regular in their arrangement than the bedding, maintaining their straight course throughout large tracts of country, and their dip changing very gradually as we cross successive planes; finally he laid down, as the result of his own researches in districts of slate-rocks, the important law, that 'where the cleavage is well developed in a thick mass of slate-rock, the *strike* of the cleavage is nearly coincident with the strike of the beds.'[1]

This last statement was modified by Professor Phillips, Dr. Darwin,[2] and Mr. Sharpe, who replaced it by the law, that the strike of the cleavage planes in a district is 'parallel to the main axes of elevation,' and not *necessarily* with the strike of the beds at any given locality. In this form the law was borne out by the researches of field-geologists[3] in all parts of the world where slate-rocks are met with. The law as enunciated by Professor Sedgwick has many exceptions, as he himself was the first to remark.

The alleged second direction of cleavage in certain slates, at right angles to the chief cleavage, as stated by Mr. D. Sharpe,[4] and subsequently by Professor Sedgwick[5] and others, is a point to be discussed below.

The next advance was the observation that the fossils associated with cleaved rocks are commonly more or less distorted in form, and that the mode of distortion is related to the direction of the cleavage-planes in the rock. This fact was first brought into notice by Professor Phillips,[6] but its significance was only subsequently made clear by Mr. Sharpe.[7] The latter geologist drew the conclusion that rocks affected by slaty cleavage have suffered a compression of their mass in a direction everywhere perpendicular to the plane of cleavage, and an expansion in the direction of cleavage-dip. The numerical results of Professor Haughton,[8] merely mentioned by Professor Phillips in an addendum, confirmed at least the former of these conclusions.

Messrs. Sharpe[9] and Sorby[10] showed that the form and arrangement of the fragments, both macro- and micro-scopic, which compose the mass of a cleaved rock, agree in every respect with the kind of distortion supposed, and made various other observations having the same bearing.

Finally, as regards the theories of slaty cleavage, Bakewell[11] and most of the earlier investigators considered the structure to be 'the effect of crystallisation'; MacCulloch[12] supposed it to be the result of 'concretionary action'; Professor Sedgwick[13] himself ascribed it to 'crystalline

and polar forces acting on the whole mass simultaneously, in given directions, and with adequate power.' Sir H. De la Beche[1] invoked the agency of electric currents and terrestrial magnetism, and cited in confirmation of this theory the experiments of Messrs. R. W. Fox[2] and R. Hunt.[3] Mr. Hopkins,[4] too, endeavoured to show a connection between cleavage and 'magnetic currents.' Dr. Charles Darwin,[5] whose views will be further referred to, was led to suspect 'that the planes of cleavage and foliation are intimately connected with the planes of different tension, to which the area was long subjected, *after* the main fissures or axes of upheavement had been formed, but before the final consolidation of the mass and the total cessation of all molecular movement.' The mechanical theory gained ground slowly, geologists being apparently reluctant to admit so simple an explanation of the phenomena. Mr. J. Beete Jukes,[6] for example, generalising from his observations in Newfoundland, wrote thus: 'The same causes which gave their prevalent and general direction to the mechanical forces by which the rocks were elevated from their original position, and their strike and dip produced, likewise determined the direction in which those forces should act (whatever they were), which produced the cleavage.' Mr. Sharpe[7] in his first paper on slaty cleavage, while admitting the action of pressure in the production of cleavage, declined to regard it as the sole agent concerned, and considered that heat may have had some share in the process; in his second paper, however, he had apparently arrived at a purely mechanical theory. But it still remained for Mr. Sorby[8] to show that all the main facts connected with slaty cleavage are explicable as the effects of a distortion of the mass of the rock consequent upon lateral compression. This theory was strengthened by the synthetic experiments of Mr. Sorby and Professor Tyndall,[9] in which a fissile structure resembling cleavage was artificially produced in various plastic substances by the agency of lateral pressure alone.

II. *The Mechanical Theory of Slaty Cleavage: the Distortion of Cleaved Rocks.*

It will be convenient at this point to put forward briefly the views of those geologists who have offered explanations of slaty cleavage founded solely on mechanical principles. These theories, however complete in themselves, are to be regarded not as the end of the investigation but rather as important landmarks by the way; for they are applicable only to the slaty cleavage structure proper in its various degrees of perfection, and there may even appear reasons for doubting whether the whole truth, even as regards roofing-slates and cleaved limestones, can always be expressed by a *purely* mechanical theory, in the sense implied here.

[7] *Quart. Journ. Geol. Soc.*, vol. iii. p. 104 (1847). *Ibid.* vol. v. p. 129 (1849).
[8] *Edinb. New Phil. Journ.*, vol. lv. p. 137 (1853). *Phil. Mag.*, 4th ser., vol. xi. p. 20, and vol. xii. p. 127 (1856).
[9] *Phil. Mag.*, 4th ser., vol. xii. p. 37 (1856).

The exponents of such theories agree in referring the structure to the action of powerful lateral pressure, and in considering that such pressure operated simply by producing a distortion of the rock-mass upon which it was exerted. They differ to some extent, according to the special examples studied by each observer, as regards the precise kind of distortion produced, and the manner in which it has affected the intimate structure of the rocks in question.

We consider first, then, the kind of distortion which the rock, regarded for the present as a homogeneous mass, is supposed to have experienced under the action of the lateral pressure. If we imagine a sphere traced in the rock previous to its distortion, the effect of any uniform strain upon the mass will be to distort this sphere into an ellipsoid. This latter surface, which may be called the *strain ellipsoid*,[1] or ellipsoid of distortion, may conveniently be taken to express by its form and position the kind of strain or distortion undergone by the rock. We shall call its principal semiaxes, in descending order of magnitude, a, b, c. If the radius of the original sphere be k, it is evident that, in general, the distortion is accompanied by a change of volume in the ratio $abc : k^3$.

Mr. D. Sharpe's[2] conclusions were drawn from an examination of the fossils in the cleaved rocks of Tintagel and South Petherwin, but he extended them to all rocks having slaty cleavage, and confirmed them by the slates of North Wales, Westmoreland, and Cumberland. He says: 'It may be asserted as probable that all rocks affected by that peculiar fissile character which we usually call slaty cleavage, have undergone

'1. A compression of their mass in a direction everywhere perpendicular to the plane of cleavage.

'2. An expansion of their mass along the planes of cleavage in the direction of a line at right angles to the line of incidence of the planes of bedding and cleavage; or, in other words, in the direction of the dip of the cleavage.[3] No proof has been found that the rock has suffered any change in the direction of the strike of the cleavage planes. We must therefore presume that the masses of rock have not been altered in that direction.'

Assuming these laws, the strain ellipsoid would have its least axis perpendicular to the cleavage-planes, its greatest axis along the cleavage dip, and its mean axis along the cleavage-strike. Also the last clause in Mr. Sharpe's results makes $b = k$, and therefore the change of volume would be represented by the ratio $ac : b^2$. Mr. Sharpe speaks of the compression being 'compensated' by the expansion; if this is to be interpreted strictly, we should have $ac = b^2$, and no change of volume; but it is highly probable that in most cleaved rocks, ac would be less than b^2, and the volume would be reduced in proportion.

Dr. H. Clifton Sorby[4] examined the slates of Penrhyn and Llanberis, and the cleaved limestones and dolomites of Devonshire, and drew con-

[1] Thomson and Tait, *Natural Philosophy*, vol. i. pt. i. § 160, new ed. (1879). Minchin, *Treatise on Statics*, § 280, new ed. (1880).

[2] 'On Slaty Cleavage,' *Quart. Journ. Geol. Soc.*, vol. iii. p. 87 (1847).

[3] The latter form of statement must be preferred; the two expressions are clearly not equivalent, unless the strikes of the cleavage and the bedding coincide.

[4] 'On the Origin of Slaty Cleavage,' *Edinb. New Phil. Journ.*, vol. lv. p. 137 (1853). 'On Slaty Cleavage as Exhibited in the Devonian Limestones of Devon,' *Phil. Mag.*, 4th ser., vol. xi. p. 20 (1856).

clusions entirely in agreement with those of the geologist just quoted. It appears from his observations that a common form for the strain ellipsoid in the slates of North Wales is one whose axes are in such ratios as 1·6 : 1 : 0·27. These figures indicate a total diminution of volume in the ratio 0·43 : 1.

Professor S. Haughton [1] made numerical calculations of the distortion of form exhibited by the fossils of cleaved rocks, examining specimens from eight localities in Ireland, Cornwall, and Wales. He found a very marked compression in the direction perpendicular to the cleavage-planes, but his results led him to reject Mr. Sharpe's other laws relating to the expansion along the cleavage-dip and the unchanged dimensions along the cleavage-strike. His ellipsoid of strain was thus an oblate spheroid or ellipsoid of revolution, having its equator in the cleavage-plane. This implies, either no expansion in any direction, or equal expansion in all directions along the cleavage-planes. In the former case the diminution of volume would be in the ratio $c : b$ (or $c : a$); in the latter the diminution of volume, if any, would be indeterminate by this method. Professor Haughton's results, expressed in the notation already employed, are given in the following table:—

		Ratios of axes of ellipsoid
1	Carboniferous slate of Ardroginna, Waterford . .	0·975 : 1·000 : 0·412
2	" " South Petherwin, Cornwall .	1·010 : 1·000 : 0·256
3	" " Tintagel, Cornwall . .	0·669 : 1·000 : 0·102
4	Lingula beds of Abereiddy Bay, Pembrokeshire .	1·000 : 1·000 : 0·145
5	Green grits of Llyn Padarn, Llanberis . . .	0·805 : 1·000 : 0·531
6	Silurian black slates of Moel Benddu, North Wales .	1·000 : 1·000 : 0·270
7	" " Garth, Portmadoc . .	1·000 : 1·000 : 0·090
8	Carboniferous slate of Carrigaline, Co. Cork . .	1·000 : 1·000 : 0·466

In the last three examples it is *assumed* that a and b are equal, and c is calculated on this assumption, which seems scarcely warranted by the results obtained for the first five rocks examined. It will be noticed that Professor Haughton's investigations included the fossils on which Mr. Sharpe based his conclusions, but the more perfectly cleaved roofing slates, such as those of North Wales, studied by Dr. Sorby, are excluded, owing to the absence of fossils in them.

Professor J. Phillips,[2] in an early paper read before the British Association, described the distortion of cleaved rocks as a 'creeping movement among the particles of the rock, along the plane of cleavage, the effect of which was to roll them forward, in a direction always uniform over the same tract of country.' This rather indefinite language may be interpreted to mean what would now be termed a shearing motion [3] along the cleavage planes. In other words, if we conceive the rock divided into indefinitely thin slices, parallel to the cleavage planes, then each slice is supposed to have slipped an indefinitely small distance over its neighbour in the direction of the cleavage dip; the relative dis-

placement of any two distant slices being proportional to the distance between them, and equal to s times that distance, where s is called the measure of the shear. A square (ABCD, fig. 1) would be distorted by the shear into a parallelogram (ABCD, fig. 2); and the ratio BE : AE would be the measure of the shear. The axes of the ellipsoid of strain would be in the ratios

$$\frac{\sqrt{s^2+4}+s}{2} : 1 : \frac{\sqrt{s^2+4}-s}{2}.$$

One set of circular sections of the ellipsoid would coincide with the cleavage planes, and its major axis would make with these planes the angle whose tangent is $\frac{b}{a}$. The axes would be such that $ac = b^2$, and there would be no change of volume in the rock during distortion.

FIG. 1.

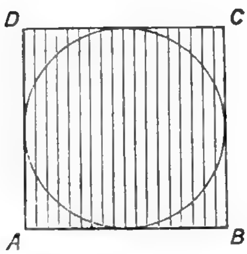

FIG. 2.

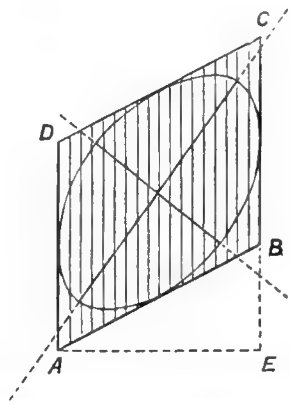

M. Aug. Laugel[1] also regarded cleavage planes as planes along which a shear (*glissement*) of the rock has taken place. It is easily seen, however, that such an idea is entirely incompatible with the observed facts. For the kind of distortion described implies (i.) no compression of the rock in a direction perpendicular to the cleavage planes, and (ii.) no distortion of plane objects lying in planes parallel to the cleavage planes. Moreover, as will appear in the next section, any mechanical theory of true slaty cleavage requires that the cleavage planes should be perpendicular to the least axis of the ellipsoid of strain.

Accordingly the Rev. O. Fisher, who formerly endorsed the theory just mentioned,[2] was led to change his opinion, and, while still describing the distortion of slate-rocks as a shear, to suppose that the shearing has taken place, not along the cleavage planes, but in such a direction that these planes are perpendicular to the least axis of the resulting strain ellipsoid.[3] But if there be, as seems to be indicated by the facts of cleavage, a diminution of volume during the process, the distortion of the rock cannot be resolved into shearing; and if, on the other hand, as Mr. Fisher maintains, there be little or no change of volume, it still seems simpler, as I have contended,[4] to describe the movement as a compression

perpendicular to the cleavage-planes accompanied by a *compensating* expansion along the cleavage-dip, for to this his shearing, with the necessary rotation concurrent with it, may be reduced. In this case the strain ellipsoid, having b a mean proportional between a and c, differs both from that of Dr. Sorby, in which b is greater than that mean proportional, and from that of Professor Haughton, in which $a = b$.

Finally, it seems reasonable to suppose that the precise kind of distortion produced in a rock by powerful lateral pressure depends on the nature of the rock itself and on the intensity and duration of the pressure. We may perhaps distinguish, as I have elsewhere suggested,[1] three stages of the process, at any one of which it may be arrested. In the first stage the rock-mass yields by a simple lateral compression with no considerable expansion to compensate it; the volume is accordingly diminished, this being effected by the closer packing of the constituent fragments and the expulsion of the greater part of the interstitial water. In the second stage the limit of this packing has been reached, and further lateral compression is therefore compensated by expansion along the cleavage-dip, there being no diminution of volume. In the third stage the intense pressure facilitates chemical changes in the rock, involving a further diminution of bulk, and so a lateral compression only partially compensated by expansion along the cleavage-dip. The strain ellipsoid of Professor Haughton would characterise the first stage, that of Dr. Sorby the latter stages of the process.

A rock may, of course, be operated upon, either successively or simultaneously, by pressures in two or more directions, and the cleavage-structure will be determined by the resulting distortion. For instance, there may be compressions in two directions and an expansion in the direction perpendicular to both, producing a very prolate strain ellipsoid, in which b and c are nearly equal and a considerably greater. In this case the rock would have the fibrous structure which Professor A. Heim[2] denominates *linear* cleavage as distinguished from ordinary plane cleavage, and which has been artificially imitated in the well-known experiments of MM. Tresca[3] and Daubrée.[4] Instead of a plane of cleavage there is an axis of cleavage.

III. *The Mechanical Theory of Slaty Cleavage: the Intimate Structure of Cleaved Rocks.*

The direct evidence for the distortion of cleaved rocks and the methods of arriving at a numerical estimate of it will be treated in the next section. At present we have to consider what effect such distortion has upon the intimate structure of these rocks, and how slaty cleavage is only a logical consequence of it.

Mr. Sharpe,[5] examining certain coarse brecciated bands in the slate quarries of Langdale and Patterdale, noticed that the included large fragments, of which the rock was to a great extent made up, were compressed perpendicularly to the cleavage-planes and elongated along the cleavage-dip, thus approximating, when allowance was made for their

irregular shapes, to an almond-like or ellipsoidal form. Observing with a glass the fine-grained slates, he was of opinion that they too presented the same structure on a small scale, their minute constituent fragments tending to the general form of ellipsoids with their shortest axes perpendicular to the cleavage-planes and their longest axes along the cleavage-dip. He pointed out that a rock having this constitution would, in consequence, split most readily in a direction perpendicular to the shortest axes of the ellipsoids, and so to the greatest compression of the rock-mass, for such a surface of fracture would run along the flattest faces of the fragments and meet the smallest number of them. The cleavage perpendicular to the direction of greatest compression in the rock was thus accounted for. Mr. Sharpe also maintained that there would be a second, though less perfect, cleavage perpendicular to the strike of the first, and so parallel to what the workmen call the 'side' of the slate; but we shall see that this could not be called a direction of cleavage in the strict sense of the word.

The author quoted considered, then, that the distortion of the rock-mass was shared by the ultimate fragments composing it. Dr. Sorby, on the other hand, held that the yielding of the rock was effected by a sliding of the originally flat or linear fragments over one another and a re-arrangement of them approximately perpendicular to the greatest compression of the rock. He supposed that the rocks which now form slates were originally composed, to a large extent, of flat and linear elements: in the slates of Penrhyn, of Llanberis,[1] about half the bulk of the rock consists of minute flakes of mica averaging $\frac{1}{1000}$ inch in length and $\frac{1}{10000}$ inch in thickness; in the Devonian limestones of Devonshire[2] fragments of crinoids and corals play a similar part. In certain uncleaved rocks of like composition the fragments lie in all directions at random, and we may suppose that the slate-rocks and limestones in question had originally a similar constitution. When the rock experienced a lateral compression and an expansion in a direction perpendicular to it, the fragments moved with the mass; there was thus a tendency in the flat constituents to set themselves perpendicular to the direction of the greatest compression, and in the linear fragments to arrange themselves not only approximately perpendicular to the compression, but also roughly parallel to the direction of expansion. In this way a structure would be set up in the rock effectively the same as that supposed by Mr. Sharpe, but arising in a different way. Premising that the two theories are by no means mutually exclusive, we may go on to consider that of Dr. Sorby more closely.

Conceive a number of planes traced in the rock, having the same 'strike' as the cleavage, and arranged, previously to the distortion, at equal angular intervals: fig. 3 shows the traces of such planes on a plane perpendicular to the cleavage-strike. After the distortion of the whole it is clear that all the planes will have been turned so as to make smaller angles with the plane perpendicular to the greatest compression, or, in other words, the principal diametral plane of the strain-ellipsoid; and, further, the planes in the neighbourhood of that plane will be more closely packed together than those more remote (fig. 4). In fact, if θ be the angle made before distortion by any one of these planes with the plane

[1] *Edinb. New Phil. Journ.*, vol. lv. p. 137 (1853). *Phil. Mag.*, 4th ser., vol. xii. p. 127 (1856).

[2] *Phil. Mag.*, vol. xi. p. 20 (1856).

perpendicular to the greatest compression, the angle θ' which it makes after distortion will be given by the equation

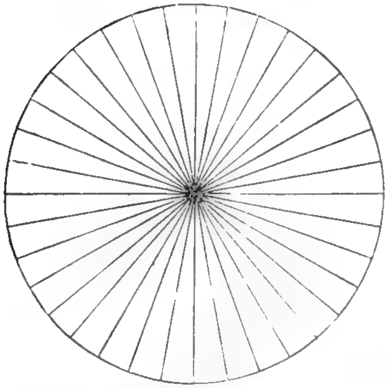
$$\tan \theta' = \frac{c}{a} \tan \theta\,;$$

and if the number of such planes be indefinitely great, the closeness of their arrangement, after distortion, in the neighbourhood of the plane considered will be proportional to

$$\frac{\cos^2\theta}{\cos^2\theta'} \times \frac{a}{c}$$

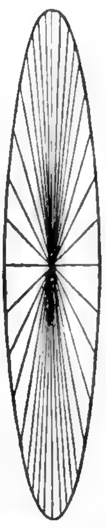
This expression becomes $\frac{a}{c}$ for $\theta'=0$, and $\frac{c}{a}$ for $\theta'=90°$; so the degree of closeness of the planes in the neighbourhood of the principal diametral plane of the strain ellipsoid is to that in the neighbourhood of the plane perpendicular to it in the ratio $a^2 : c^2$. Now let all these planes represent

FIG. 3.



Before compression and elongation.

FIG. 4.



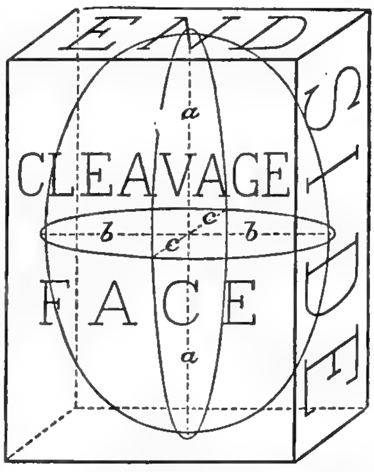
After compression and elongation.

flat fragments such as scales of mica originally arranged at random through the rock, and suppose the distortion such that $a = 6c$. Then after distortion the number of scales of mica making angles of less than 1°, say, with the principal diametral plane will be about 36 times the number making angles of less than 1° with the plane perpendicular to it; and it is easy to see that the rock must split with much greater readiness along the former plane than along the latter. The number 36, however, cannot be taken as giving any precise indication of the relative facilities of splitting in different directions, for, in the first place a slate-rock is not wholly made up of flat and linear particles, and secondly, the above mode of demonstration—that followed by Dr. Sorby and Professor Phillips—takes account only of those flat particles whose planes have their strike perpendicular to the direction of compression, or of linear particles whose long axes lie in vertical planes parallel to the direction of compression. A stricter investigation would be too tedious for insertion here. It is sufficient to notice that, according to the mechanical theory

here developed, of all planes passing through *b* (fig. 5), the facility of splitting is a maximum for that plane which also passes through *a*, and a minimum for that which passes through *c*. It is easy to see, from considerations precisely similar, that, of all planes passing through *c*, the facility of splitting is a maximum for that passing through *a* and a minimum for that passing through *b*: and, of all planes passing through *a*, the facility of splitting is a maximum for that passing through *b*, and a minimum for that passing through *c*. Summarising these conclusions, we may say that the plane through *a* and *b* gives a maximum, and that through *b* and *c* a minimum among all other planes in the rock, while the plane through *a* and *c* gives a maximum among all planes through *c*, and a minimum among all those through *a*. With respect to these results, two remarks may be made.

In the first place, the principal diametral plane of the strain ellipsoid which passes through *a* and *b* is the cleavage-plane *par excellence*; but the facility of cleavage along other planes nearly parallel to it is nearly as great, and it is evident that under suitable stresses the rock will split along any plane making a small angle with the true cleavage direction. This is not a truism, but a consequence of the fact that the facility of splitting along the true cleavage is a *maximum* in the proper mathematical sense, and varies continuously from that plane; the same would not be true of the crystalline cleavage of minerals.

Fig. 5.



The other point to be noticed is that, on this theory, there can be but one true cleavage direction: a plane parallel to the 'side,' *i.e.*, the plane passing through *a* and *c*, is not a cleavage-plane in the sense just indicated. For although the facility of cleavage along such a plane is a maximum for all planes passing through *c*, it is a minimum for all planes passing through *a*. A similar argument holds good on Mr. Sharpe's theory of the constitution of slate-rock, and his 'secondary cleavage' seems to be no more than the properties of 'side' referred to below, in Section VI. It has been suggested[1] that a second cleavage might arise from the action of a second and subsequent lateral pressure, operating in a different direction from the first one. But this is not the case, for after any combination of uniform compressions and expansions of the rock, the strain surface will still be an ellipsoid, and the line of argument indicated above will hold for this final or resultant strain ellipsoid.

In the case of the fibrous or 'linear' cleavage mentioned above, a phenomenon of only local occurrence, if we suppose $b = c$, the facility of cleavage along all planes passing through *a* will be the same, and greater than that along any other plane. In the case of Professor Haughton's strain ellipsoid, in which $a = b$, it will be seen that the facility of cleavage will be the same for all planes passing through *c*, which is incompatible with the distinctive properties of the 'side' and 'end,' recognised by the quarrymen in all the best roofing-slates.

[1] *Quart. Journ. Geol. Soc.*, vol. v. p. 116 (1849), &c.

I have not thought it necessary in the foregoing *résumé* to discuss all the views concerning cleavage propagated prior to the development of the mechanical theory, since they were, for the most part, founded on very meagre evidence as to the facts. Mr. W. Hopkins,[1] for instance, concluded from mathematical considerations, that, if the direction of the cleavage-planes in a rock be determined by stresses to which it has been subjected, those planes ought to be either perpendicular to the direction of maximum normal pressure, or parallel to the planes of maximum tangential stress, which make angles of 45° with the maximum normal pressure. From an examination of Mr. Sharpe's distorted fossils only, he was led to fix on the latter supposition, whereas the truth of the former, which was that embraced by Mr. Sharpe himself, has since been amply confirmed.

Neither have I noticed explicitly the objections brought against a mechanical explanation of slaty cleavage by Professors Sedgwick,[2] H. D. Rogers,[3] and others, for such objections are found to disappear on a fuller examination of both the theory and the facts, and are indeed implicitly answered by the more complete exhibition of that theory in its various applications.

IV. *The Mechanical Theory of Slaty Cleavage: the Direct Evidence of the Distortion of Cleaved Rocks.*

The most obvious information regarding the distortion which cleaved rocks have undergone is that derived from the contortions produced in intercalated beds of less yielding materials. A typical example in the cliffs near Ilfracombe was described and figured by Dr. Sorby,[4] and has been frequently copied.[5] Here a bed of coarse-grained sandy slate occurs among fine-grained shaley slate, and is seen to have been forced into a series of bold undulations, although the bedding at a short distance above and below is undisturbed. The axial planes of the undulations coincide with the cleavage-planes of the finer slate,[6] and the thickness of the sandy bed at the troughs and crests of the undulations is four times the thickness at the intermediate places. The clear interpretation of this section is that the whole has undergone a lateral compression of considerable amount, partly compensated by yielding in an upward direction perpendicular to the compression; and further, that the direction of compression, as deduced from the position of the axial planes of the folds, is at right angles to the cleavage-planes. Similar phenomena may be observed in almost any of the slate-quarries of North Wales.

Dr. Sorby also made use of the evidence of the greenish spots, apparently of concretionary origin, which are of common occurrence in the Welsh roofing-slates examined by him. These spots may be assumed

to have been originally spherical, or perhaps slightly extended in the direction of the stratification so as to form a rather oblate spheroid; but their present shape is that of an ellipsoid of three unequal axes, viz., the greatest axis in the plane of cleavage and along its dip; the mean axis in the plane of cleavage and along its strike; the least axis perpendicular to the plane of cleavage; thus indicating a compression perpendicular to the cleavage-planes, and an expansion along them in the direction of their dip. In fact, if the original form was spherical, the present form of these spots must give us the strain ellipsoid itself. If, however, as suggested by Mr. Fisher,[1] the formation of these spots be posterior to that of cleavage, we must account for their form by 'the chemical influence spreading most readily along the grain of the slate, and with greatest difficulty across its laminæ,' and in this case no quantitative conclusions can be drawn from the phenomena.

The most valuable evidence of the nature and amount of the distortion of cleaved rocks is that obtained by noting the altered forms of contained fossils. The merit of first applying numerical calculation to this line of inquiry belongs to Professor Haughton,[2] whose work has already been alluded to. We are, however, not justified in assuming that the deformation of the fossils is invariably a correct measure of the distortion of the rocks themselves. A hard substance imbedded in a softer matrix would evidently yield but slightly, or not at all, to any compression to which the mass as a whole might be subjected; and it is a matter of common observation that in many slate-rocks those fossils of more solid substance or stouter form are comparatively unchanged in shape, while those of slighter build exhibit a marked deformation. It might be possible by noting the degrees of distortion of different kinds of fossils in the same rock to form some idea of the consistency of that rock at the time of its deformation. Meanwhile, it may be remarked that the distortion of the rock as deduced from the forms of its contained fossils will be in all cases an under rather than an over-estimate; and where different kinds of fossils in the same rock exhibit deformation to the same extent, we may reasonably suppose that they have all shared to the full the distortion of the rock itself.

Taking this last case, it is clear that the degree of distortion of the fossils must be in direct relation with the form of the strain ellipsoid, so that with sufficient data the latter may be deduced from the former. It will be convenient to adopt the usual assumption that the bedding and cleavage have the same strike, and to regard the fossils as plane figures lying parallel to the bedding.

Fig. 6 is taken in a plane perpendicular to the common strike of bedding and cleavage. The ellipse is the section by this plane of the strain ellipsoid, AOA′, COC′, are the greatest and least axes of the ellipsoid; POP′ is the trace of the bedding-plane, and the angle AOP is the angle between the planes of bedding and cleavage, which we shall call ϕ. If the radius OP be called ρ, then

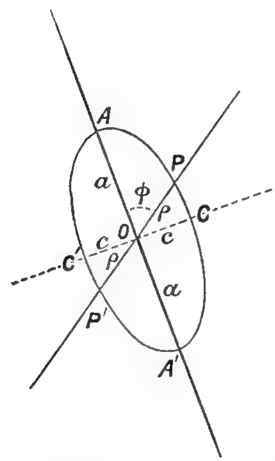
$$\frac{1}{\rho^2}=\frac{\cos^2\phi}{a^2}+\frac{\sin^2\phi}{c^2} \quad \text{(i.)}$$

The plane of bedding cuts the strain ellipsoid in an ellipse whose semi-axes are ρ and b, and this may be called the strain ellipse for objects

[1] *Geol. Mag.*, 1884, p. 402. [2] *Phil. Mag.*, 4th ser., vol. xii. p. 409 (1856).

lying in the plane of bedding, since its form expresses completely the distortion of such objects. If the radius of the original sphere before distortion be k, the dimensions of any fossil lying in the bedding-plane have been altered in the ratio $\rho : k$ along the dip, and in the ratio $b : k$ along the strike. If there be no alteration along the direction of the strike, $b = k$; but without making this assumption, we may say, in Professor Haughton's terminology,[1] that the *distortion* along the dip is $\frac{\rho}{b}$, or the distortion along the strike $\frac{b}{\rho}$.

FIG. 6.



It is of importance to notice that although the rock is supposed to undergo an expansion along the *cleavage*-dip, the distortion along the dip of the *bedding* may be either an expansion or a compression, according as the angle between the bedding and the cleavage is small or great; for it is easy to see from equation (i.) that ρ may be either greater or less than b. If the bedding-plane happen to make such an angle with the cleavage that $\rho = b$, its strain ellipse is a circle, and the fossils suffer no deformation in the bedding-plane. It follows from equation (i.) that in this case

$$\tan^2\phi = \frac{\frac{1}{b^2} - \frac{1}{a^2}}{\frac{1}{c^2} - \frac{1}{b^2}};$$

for smaller values of ϕ, ρ is greater than b, and the distortion of the fossils is a relative expansion along the dip of the bed; for greater values of ϕ, ρ is less than b, and the distortion is a compression along the dip. If, as Professor Haughton maintains, in the rocks examined by him, the strain ellipsoid be one of revolution, having $a = b$, the circular sections must be parallel to the cleavage. In this case there will be no deformation of fossils when the bedding and cleavage coincide, but in every other position of the bedding relatively to the cleavage there will be a compression of the fossils in the direction of the dip. These conditions do not appear to be always verified even in the localities studied by Professor Haughton.[2] Reverting, then, to the general case, it is manifest that the distortion along the dip is an expansion $\frac{a}{b}$ when the bedding and cleavage coincide, and a compression $\frac{c}{b}$ when they are at right angles. For any other position the distortion $\frac{\rho}{b}$ may be determined from the equation

$$\left(\frac{b}{\rho}\right)^2 = \left(\frac{b}{a}\right)^2 \cos^2\phi + \left(\frac{b}{c}\right)^2 \sin^2\phi \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (\text{ii.})$$

[1] *Loc. cit.* p. 410. There seems to be some obscurity here. The only two lines which are at right angles to one another, both before and after distortion, are those parallel to the dip and strike respectively.

[2] *E.g.*, in the Portmadoc district, both in the Lingula Flags of Borth and the Tremadoc beds of Garth Hill.

By observing the distortions $\frac{b}{\rho}$ and $\frac{b}{\rho'}$, for two places in the same locality where the bedding makes angles ϕ and ϕ', respectively, with the cleavage, we can calculate the ratios of the axes of the strain ellipsoid. For it is easy to show that, from equation (ii.) and the corresponding one, we obtain

$$\left(\frac{b}{a}\right)^2 = \frac{\left(\frac{b}{\rho'} \sin \phi + \frac{b}{\rho} \sin \phi'\right)\left(\frac{b}{\rho'} \sin \phi - \frac{b}{\rho} \sin \phi'\right)}{\sin (\phi + \phi') \sin (\phi - \phi')} \quad . \quad . \quad \text{(iii.)}$$

$$\left(\frac{b}{c}\right)^2 = \frac{\left(\frac{b}{\rho} \cos \phi' + \frac{b}{\rho'} \cos \phi\right)\left(\frac{b}{\rho} \cos \phi' - \frac{b}{\rho'} \cos \phi\right)}{\sin (\phi + \phi') \sin (\phi - \phi').} \quad . \quad . \quad \text{(iv.)}$$

The practical question is, then, how to determine the distortion $\frac{\rho}{b}$ for any position of the bedding-plane by observations of deformed fossils in that plane. Let us call the *length* of a fossil, such for instance as a trilobite, that line about which, in an undistorted specimen, there is bilateral symmetry, and let the *breadth* be measured along a line which before distortion is at right angles to the length. The length and breadth of a distorted fossil will not in general be at right angles to each other: they will be so only when one of them lies in the direction of dip, and consequently the other in the direction of strike. In this special case we may profitably adopt Professor Haughton's method, viz., comparing the relative dimensions of the distorted fossil with the known relative dimensions of the species when undistorted. If the length of the fossil lie in the direction of dip, the ratio of its length to its breadth, divided by the ratio of length to breadth in an undistorted specimen, will give $\frac{\rho}{b}$; if the breadth of the fossil lie in the direction of dip, the same calculation will give $\frac{b}{\rho}$. If on the same slab of rock occur specimens in the two positions, we can estimate the distortion without knowing the undistorted form of the species; for if we divide the ratio of length to breadth of a specimen in the former position by the ratio of length to breadth of a specimen in the latter, we get at once $\left(\frac{\rho}{b}\right)^2$.

A single specimen of a fossil whose length and breadth lie oblique to the dip and strike, is sufficient to determine the distortion without previous knowledge of the form of the species when undistorted. For if α and β be the angles which the length and breadth make with the direction of dip, it is readily proved that

$$\left(\frac{b}{\rho}\right)^2 = \tan \alpha \tan \beta \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad \text{(v.)}$$

This method is readily applied, and if the length and breadth make considerable angles with the dip, it is very accurate. It is tantamount to that employed by M. H. Dufet,[1] who, however, makes use of geometrical constructions.

[1] 'Déformations des Fossiles, &c.,' *Ann. de l'Ecole Norm. Sup.*, sér. 2, t. iv. p. 183 (1875).

We have already remarked that the extent to which the fossils partake of the distortion of their matrix depends necessarily on the relative consistencies of the two at the time of the distortion. It should be added, for the sake of completeness, that sometimes hard but brittle fossils, such as the guards of belemnites, have been able to resist distortion, but have yielded by fracture. In such cases the several portions of the fossil are found to be separated from one another in the direction of the cleavage dip; and we have in these rocks, not only a proof, but a direct measure (which cannot be an over-estimate) of the expansion of the rock in that direction. Examples are quoted by MM. Heim [1] and Daubrée; [2] and we may see that at the time of the distortion the rocks must have already acquired a degree of firmness and hardness, from the fact that the separation of the fragments of the fossils left cavities, which were only subsequently filled by crystallised calcite.

V. *Slaty Cleavage in Rocks of various Lithological Characters.*

Slaty cleavage is by no means confined to the rocks of any one geological period or era, but owing to its association with earth-movements on an extensive scale, the structure is, in the British Isles, characteristic of the older Palæozoic formations. The best slates of North Wales are procured from the Lower Cambrian strata, as at Penrhyn, Llanberis, and Nantlle, and from the Bala and Llandeilo beds, as at Ffestiniog and other places. The slates of the Lake District also are referred to the Bala and Arenig series, but slates of Devonian age are worked in Cornwall, and Carboniferous in Devonshire. In different parts of Europe, North America, &c., good slates are obtained from strata of Jurassic, Cretaceous, and Tertiary ages.

But although the structure is not restricted to strata of any special geological age, its association with rocks of particular lithological types has been noted from an early date. It is met with in perfection in argillaceous rocks of fine texture and in fine-grained fragmental rocks of volcanic origin. A specimen in the Woodwardian Museum shows fifty slates split from a block $3\frac{1}{2}$ inches in thickness, and in the Nantlle quarries, where this was obtained, the best slates are usually from $\frac{1}{8}$ to $\frac{1}{10}$ inch thick. The Llanberis slates are similar, and the beds at Ffestiniog are even more yielding. The degree of thinness to which the slates can be split in working depends, however, not only on the perfection of the cleavage structure, but also on the flexibility and toughness of the rock.

Some argillaceous limestones exhibit cleavage well developed, as do others, for example some in Devonshire, which are almost purely calcareous and dolomitic. In some cases a relation is observable between the percentage of argillaceous matter and the facility of cleavage. An excellent instance is furnished by a section in the Lias at Grenoble, where several beds of argillaceous limestones of different compositions are exposed, and those with the greatest amount of argillaceous matter are found to present the best cleavage. M. E. Jannettaz [3] has examined these different strata by a method which he has applied with success to

[1] *Mechanismus der Gebirgsbildung*, Atlas, Taf. xiv., figs. 1–5 (1883).
[2] *Etudes Synthétiques de Géologie Expérimentale*, p. 404 (1879).
[3] 'Mém. sur les Clivages des Roches, &c.,' *Bull. de la Soc. Géol. de France*, sér. 3, t. xii. p. 216 (1884).

other non-isotropic rocks and minerals; a method depending on the fact, that a cleaved rock conducts heat better along than across the cleavage-planes. His process is to cut a section perpendicular to the cleavage, coat the surface with a thin film of grease, and heat at one point. It is found that the curve marked out by the ridge of melted grease after its cooling is not a circle, but an ellipse whose longer axis is along the trace of the cleavage. The ratio of the axes of this ellipse indicates the relative thermal conductivity of the rock along and across the cleavage-planes, and may be regarded as, to some extent, an index of the non-isotropic character of the rock.[1] In the Grenoble section this ratio was found to be greatest in those beds which contained most argillaceous and least calcareous matter, as appears from the table quoted below.

Percentage composition		Ratio of axes of ellipse of conductivity
Argillaceous matter	Calcareous matter	
62	38	1·04

6	94	1·1
10	90	1·06

Sandstones, for the most part, are capable of taking but a very rude cleavage. In Wales the diabase dykes, so common in some slate-quarries, occasionally exhibit the same structure in a very imperfect degree.

When alternating beds of different lithological characters have been subjected alike to the forces which produce cleavage, it frequently happens, as was long ago noticed,[2] that the more fine-grained and argillaceous beds have acquired a cleavage-structure, while the coarser beds, calcareous or arenaceous, have not been so affected. Even when intercalated sandy beds among slate rocks have received a certain cleavage structure, it is not only of a more rudimentary character than that of the slate-rock, but has a slightly different angle of dip, the cleavage surfaces being bent or curved at the junction of the two kinds of rocks. Most writers on the subject of cleavage have described instances of these phenomena. In the Welsh slate quarries the 'steps' produced in the cleavage planes by the thin gritty bands of rock are very noticeable. Where the slate rock rests upon a gritty band, the dip of the cleavage is seen to change abruptly on passing from the one rock to the other, the deviation sometimes amounting to as much as 20° or 30° (fig. 7). On emerging into the slate rock again, the cleavage planes resume their original direction in a manner suggestive of the refraction of a ray of light through a plate of glass. If gritty bands of different textures occur

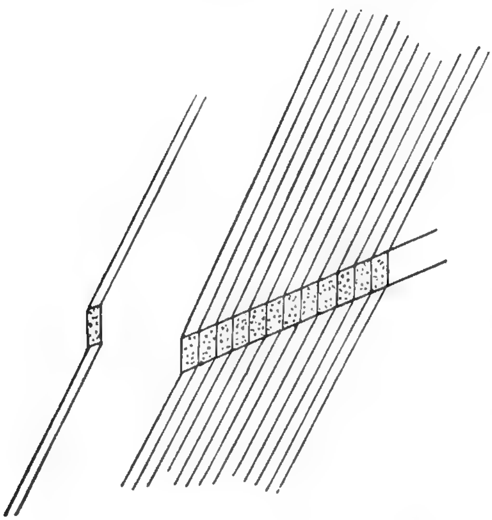
[1] This ellipse is not, however, the same as the trace of the strain ellipsoid; its axes are in the same directions as those of the latter, but less unequal. For example, in some slates from Nantlle and Groeslon, I find for the ratio of the axes of the ellipse of conductivity, by three experiments, the numbers 1·23, 1·24, 1·21; the ratio of the axes of the strain ellipse is much greater. Cf. Dufet, *Ann. de l'Ecole Norm. Sup.*, sér. 2, t. iv. p. 185 *et seq.* (1875).

M. Jannettaz has also shown that the conductivity in the direction of cleavage-dip is slightly greater than that in the direction of cleavage-strike, which is in accordance with what might be expected.

[2] *E.g.*, De la Beche, *Geological Observer*, p. 616, 2nd ed. (1853). Geikie's *Textbook of Geology*, p. 311, figs. 75, 76 (1882).

together, there may be two or more successive 'refractions' of small amount (fig. 8), and if the texture of the foreign bed change gradually upward, so as to pass into the overlying slate rock, the cleavage surfaces assume a curved form as in fig. 9.

FIG. 7.



The following rules seem to hold good in all such deviations of the cleavage surfaces :—

(i.) In passing from slate rock to a gritty band, or from a finer gritty band to a coarser, the cleavage planes are invariably bent so as to make a higher angle with the bedding.

(ii.) The deviation of the cleavage planes is of greatest amount, *ceteris paribus*, when they cut the bedding at a moderate angle. If perpendicular, there is no deviation, and if the angle be very small, the cleavage produced in the gritty band is of a very rudimentary character, the band,

FIG. 8.

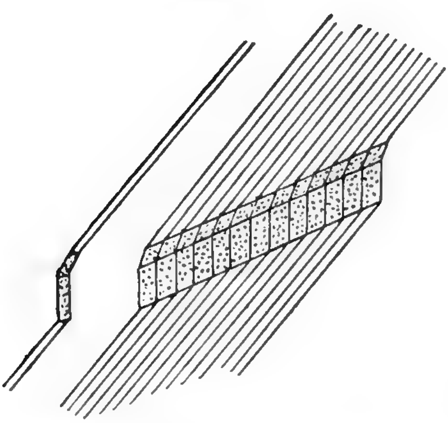


FIG. 9.

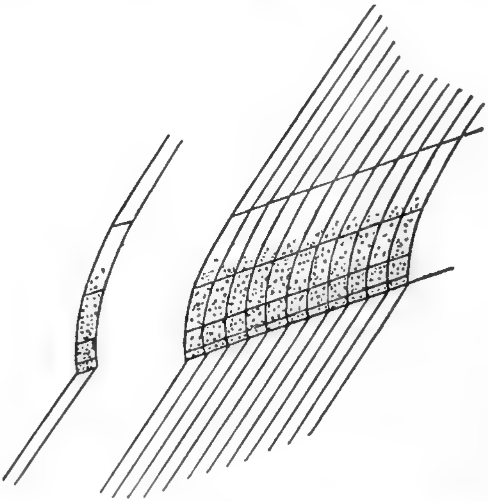

if thin, splitting in an irregular manner mainly in the direction of the bedding.[1]

[1] Professor Hughes has observed that in cleaved flagstones, 'when the cleavage-planes approach within about 15° of the stratification, the rock is apt to split along the lines of bedding.' [Lyell's *Student's Elements*, 3rd ed., p. 590 (1878).] In the Lingula flags of the Nantlle valley and of the Portmadoc district, it is easy to find wedge-shaped 'junction-specimens' of slate and flags, having opposite faces slightly inclined, one being a cleavage-plane of the slate, and the other a bedding-plane of the flags.

Good slate-rock will split truly along the cleavage-planes, however near these may be to the bedding.

Dr. Sorby[1] long ago noted similar laws, and gave his explanation of the phenomenon, which is briefly this. Since the grit yields less than the slate to the compressing force, the total voluminal compression is greater for the slate than for the grit. But near the junction of the two rocks the change of dimensions in the direction parallel to the bedding must be the same for both. Consequently, in the direction perpendicular to the bedding, the slate undergoes a less expansion (or greater compression) than the grit; and the cleavage planes, which are in each rock perpendicular to the direction of greatest compression, will therefore be less inclined to the bedding in the slate than they are in the grit.

Professor Tyndall[2] draws quite different conclusions from the phenomena in question, connecting the deflection of the cleavage planes with the progressive development of the structure concurrently with the contortion of the beds. Referring to a contorted gritty bed intercalated in slate-rock, he says: 'When the forces commenced to act, this intermediate bed, which, though comparatively unyielding, is not entirely so, suffered longitudinal pressure; as it bent, the pressure became gradually more lateral, and the direction of its cleavage is exactly such as you would infer from a force of this kind; it is neither quite across the bed, nor yet in the same direction as the cleavage of the slate above and below it, but intermediate between both.'

The latter statement seems rather obscure, and raises the question how far the production of the cleavage structure and the concomitant contortion of the strata can be regarded as contemporaneous. Dr. Sorby's exposition seems sufficient, and is a necessary consequence of the mechanical theory. To compare the theory with the phenomena we may proceed as follows.

Let a, b, c be the semiaxes of the strain ellipsoid for the slate, and a', b', c' for the grit, and let ϕ and ϕ' be the angles between the bedding and cleavage for the two rocks respectively. Referred to axes respectively parallel and perpendicular to the bedding, the Cartesian equation to the ellipse in fig. 6 is, for the slate,

$$\frac{(x\cos\phi + y\sin\phi)^2}{a^2} + \frac{(y\cos\phi - x\sin\phi)^2}{c^2} = 1 \quad . \quad . \quad . \quad . \quad . \quad \text{(vi.)}$$

The change of volume is in the ratio $\frac{ac}{b^2}$ for the slate, and $\frac{a'c'}{b^2}$ for the grit, and, consequently, if we call the ratio $ac : a'c'$, m, the equation to the ellipse for the grit is

$$\frac{(x\cos\phi + my\sin\phi)^2}{a^2} + \frac{(my\cos\phi - x\sin\phi)^2}{c^2} = 1 \quad . \quad . \quad . \quad . \quad \text{(vii.)}$$

By the usual rule for finding the axes of an ellipse, we may deduce that

$$\cot 2\phi' = \frac{\cot\phi\,(m^2a^2 - c^2) - \tan\phi\,(a^2 - m^2c^2)}{2m\,(a^2 - c^2)} \quad . \quad . \quad . \quad . \quad . \quad \text{(viii.)}$$

From this last equation it may be seen that if $\phi = 0$, $\phi' = 0$; and if $\phi = 90°$, $\phi' = 90°$; but in any other case ϕ' is less than ϕ (for m is, of

[1] *Edinb. New Phil. Journ.*, *cit.* (1853). Cf. Professor H. D. Rogers, *Trans. Roy. Soc. Edinb.*, vol. xxi. p. 449 (1856).

[2] *Phil. Mag.*, 4th ser., vol. xii. p. 43 (1856).

course, less than unity). This is in accordance with the rules stated above, as deduced from observation. To obtain a numerical test, suppose that, during the process which results in the cleavage structure, the slate is reduced to half its former volume, while the grit remains unchanged in bulk, so that $m=\frac{1}{2}$. Suppose, too, that the distortion of the slate is such that $a=6c$; then equation (viii.) becomes

$$\cot 2\phi' = \frac{8}{35}\cot\phi - \frac{143}{140}\tan\phi; \quad \ldots \ldots \quad \text{(ix.)}$$

from which we can find ϕ' when ϕ is known. Thus, if $\phi=45°$, we get $\phi'=64° \ 12'$, and therefore the deflection of the cleavage planes would be $19° \ 12'$; or if $\phi=30°$, we get $\phi'=46° \ 45'$, and so a deflection of $16° \ 45'$. These figures agree very well with observation.

As an approximate rule, when the slate is strongly cleaved, we may use the equation

$$\tan\phi' = \tan\phi \div m, \quad \ldots \ldots \quad \text{(x.)}$$

which results from neglecting the quantity $\frac{c^2}{a^2}$ in equation (viii.).

Another peculiarity of contorted gritty bands intercalated among slate rocks may be investigated by means of the above considerations—viz. the fact that a thin band of this kind is found to be thickened at the crests and troughs of the undulations (where the band is cut perpendicularly by the cleavage), and more attenuated at the intermediate places. In order to find a' and c' from equation (vii.), we may make use of the relation

$$\frac{1}{a'^2}+\frac{1}{c'^2}=\frac{\cos^2\phi+m^2\sin^2\phi}{a^2}+\frac{\sin^2\phi+m^2\cos^2\phi}{c^2},$$

which reduces to

$$a'^2+c'^2=\frac{1}{2m^2}\left\{(1+m^2)(a^2+c^2)-(1-m^2)(a^2-c^2)\cos 2\phi\right\}. \quad \text{(xi.)}$$

This equation, together with the one

$$a'c'=\frac{ac}{m}, \quad \ldots \ldots \quad \text{(xii.)}$$

suffices to determine a' and c'; and since the values thus obtained depend upon ϕ, the distortion of the gritty band will vary in different parts. It is greatest, as appears from equations (xi.) and (xii.), where $\cos 2\phi$ is least—*i.e.* where $\phi=90°$, or at the crests and troughs of the folds. At these places the thickness of the band is increased in the ratio $\sqrt{\left(\frac{2a}{c}\right)}$, which, with the numerical data assumed above, is 3·46. These numerical results accord very closely with what I have noted in the slate districts of North Wales.

Other peculiarities at the junction of slate-rock with a more gritty bed may be explained in a similar manner. One of these characters was mentioned and figured by Dr. Sorby in the Ilfracombe section already mentioned. On approaching the gritty band, which shows a series of contortions, the cleavage-planes of the slate are seen to curve slightly away from the crests of the folds, in a manner suggestive of 'stream-

lines' meeting an obstacle, and in fact for a similar reason. Very perfect examples of this peculiarity are sometimes seen in North Wales, *e.g.*, near the Dorothea Quarry, Nantlle.

Again, we may occasionally observe that where slate with a cleavage oblique to its bedding adjoins a harder bed or even such obstacle as a sheet of quartz along a joint-fissure,[1] the cleavage of the slate is slightly turned aside on approaching the harder bed, so as to make a smaller angle with it. Here a similar explanation may hold, as has been remarked by Mr. Sharpe. M. Laugel,[2] however, ascribed this phenomenon to a certain amount of shearing (*glissement*) along the planes of bedding, subsequently to the setting up of the cleavage structure; and there seem to be some cases of irregularity in cleavage-surfaces to which this explanation applies, as suggested by Professor T. McKenny Hughes.[3] There may even be a bending or crumpling of the cleavage-surfaces where they meet planes which are not those of bedding,[4] for it is obvious that those surfaces must share all subsequent vicissitudes of the rocks in which they occur. In the cases figured by Sir H. De la Beche[5] it is possible, as he suggested, that the beds have shrunk owing to the abstraction of some constituent by solution.

VI. *The Mode of Working Slate-Rock in the Quarries.*

The behaviour of slate-rock when broken and split agrees perfectly with its intimate structure as described in the foregoing pages. Besides the cleavage, the Welsh quarrymen[6] recognise in slate a certain 'grain' giving the rock different properties along different directions in the cleavage-plane. The facts are completely in accord with the deductions made above as the results of the mechanical theory. A slate breaks across the cleavage more readily parallel to its 'length' or 'side,' *i.e.*, the cleavage-dip, than it does parallel to its 'breadth' or 'end,' *i.e.*, the cleavage-strike. In a case where it is difficult to ascertain by merely looking at a block which is its length and which its breadth, the quarryman tries to find a chip on its surface: on striking this with a hammer it is found to break (*stolpio*) parallel to the length or side of the block.

In breaking across the massive blocks or slabs of rock which are afterwards to be split into roofing-slates, the same peculiarity of structure shows itself. If a block is to be broken lengthwise, it is sufficient to cut a slight groove at one end, place the edge of a chisel on it, and strike a blow with a hammer. The cut travels tolerably straight along the length of the block, although its surface often becomes grooved and fluted towards the further end. The object of the groove is to steady the chisel for the first blow, and in cutting smaller blocks it may be dis-

[6] The following remarks apply more particularly to the Lower Cambrian slates of North Wales. I am greatly indebted to C. W. Rathbone, Esq., Manager of the Pen-y-bryn Quarry at Nantlle, who has afforded me every opportunity of examining the working of the slate-rock, and to Messrs. J. T. Parry and John Roberts, of the same quarry, who have kindly given me the benefit of their large practical experience.

pensed with. For cutting across a block in a direction parallel to the 'end,' a circular saw worked by steam is employed in the larger quarries, and when the operation is performed by hand it requires much more care than cutting in the other direction. The method employed is to cut and carefully smooth a groove in one 'side' of the block, then turn it over and strike a heavy blow with a mallet upon the opposite point of the other 'side.' If the 'side' is smooth and perpendicular to the cleavage-face, a cut may be started with a chisel instead of the groove, but for a block whose 'sides' are 'bevel' the method described above must be adopted.

Again, in splitting the blocks into slates, the split is always effected from 'end' to 'end,' because it is thus less liable to 'run out' across the cleavage than if the operation were attempted from the 'side.' There are, however, in some parts of North Wales certain 'veins' or beds of slate which can be cleaved from the 'side.' In this case, too, the blocks can be cut across by the same process as that described for cutting them lengthwise. Such 'veins' are said by the quarrymen to have 'no length and breadth,' and we may suppose that in them the strain ellipsoid is one of rotation, as in Professor Haughton's calculations. Certain beds of slate which are rather coarse-grained at the bottom and grow finer upwards, must be split always from the *top* 'end'; such is the case in some of the Ffestiniog veins.

The fine striæ seen on the surface of a slate, and regarded by Mr. Fisher[1] as an arrangement analogous to 'craig and tail,' connected with the shearing movement of the rock-mass, seem, however, to be dependent less on the 'grain' than on the method of splitting the rock into slates. When a block has been roughly split off by a blow upon a chisel applied at the end, it is seen that the striæ are not straight and parallel, but diverge in curves from the point of percussion, and sometimes from harder lumps or bands in the slate. This appearance is not observable in a slate split in the ordinary way, for the cleavage is opened by two broad chisels inserted at the end, and the resulting surface shows therefore a system of roughly straight and parallel striæ, as may be well seen on wetting a cleavage-face of an ordinary roofing-slate.

The mode of splitting a block into slates also illustrates the internal structure of the rock. A block is taken of sufficient thickness to yield say eight slates; this is split into two 'fours,' each of these into two 'twos,' and finally each of the latter into two slates. In this last stage of the process there is a tendency for the split to 'run out' to the face of the slate on the weaker side. Accordingly, after starting the split at one 'end' by two broad chisels driven in with a hammer, the workman watches its progress carefully, and on seeing it deviate from the true cleavage, he draws it back by slightly bending the stronger half. This tendency of the split to 'run out' is strongest in the harder 'veins' or beds and in blocks which have been indurated by proximity to a dyke (a peculiarity known as *hollt gron*, or 'round cleavage'). In this case the quarryman sometimes has to mark or guide the cleavage all round the edge before beginning to open it, especially in cleaving the thickness of two slates. In the softer beds, on the other hand, there is a liability to break in the process of splitting, and the workman is sometimes obliged to use a long flat chisel, or 'driver,' which he forces into the split with a mallet.

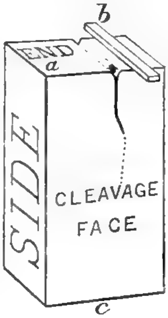
The successful splitting of the slate-rock depends on its possessing a

[1] *Geol. Mag.*, 1884, p. 269.

certain degree of flexibility, and to this flexibility the 'quarry water' or natural moisture of the rock is essential. The blocks must therefore be worked while fresh from the quarry; even an exposure of a day or two makes an appreciable difference in the facility of cleavage, and in dry weather the men are careful to keep the blocks well watered. The softest rock, which is the easiest to cleave when fresh, becomes the most difficult if allowed to dry.

The tendency of the split to 'run out' to the face of the slate and the manner in which it can be drawn back are instances of the fact which we have found to be a necessary consequence of the mechanical theory, viz., that the rock will split at a small angle with the true cleavage-planes under the action of suitable stresses. It is well known that a 'false cleavage,' slightly oblique to the direction of the true, is often obtained. Such is the case on the faces of the blocks when they are roughly split off with a thick chisel and hammer. In blasting, too, the fracture is commonly slightly oblique to the true cleavage direction, and often curves away from it at a considerable angle in the neighbourhood of a 'fast' foot-joint. In these cases the surface of the false cleavage is *not* a rough surface consisting of portions of successive true cleavage-planes, but a surface as smooth as that of an ordinary slate.

FIG. 10.



With reference to the so-called 'secondary cleavage' parallel to the 'side,' the mode of treating the blocks of slate-rock in the quarries is again instructive. In cutting a block lengthwise, parallel to the 'side,' a tendency to 'run out' towards one side may be shown (fig. 10). To bring back the crack, a flat bar of iron (*b* in the figure) is laid across the end, near the groove and towards the weaker side, and this is struck with a hammer. The effect is to bring back the crack as shown by the dotted line. This is the most approved method; the old-fashioned plan was to place a lump under the block, immediately below the crack (at *c*), and then to strike with a mallet on the upper end, at the corner (*a* in fig.) next the stronger side. This was less accurate than the other method described, besides presenting the danger of breaking the block at the corner struck. It is easy to see why the deviation of the cut in this case should be greater than that of the 'false cleavage,' for (referring to fig. 5) though the tendency to split along the 'side' is a maximum among all planes parallel to the axis *c*, the maximum is much less sharply defined than in the case of the cleavage proper. The face of a fracture parallel to the 'side,' also, is much less smooth and regular than a cleavage face, and is frequently fluted and grooved. Indeed, it may safely be asserted that no evidence of anything that can fairly be described as a second cleavage is to be found in the slate workings of North Wales. The structure known as 'cross-cleavage,'[1] the *gwniad* of the quarrymen and the 'lace' of slate merchants, which renders worthless much otherwise valuable rock, is only a system of secret jointing.

M. Jannettaz,[2] however, asserts that the *longrain* of the Ardennes slates is a true second cleavage, but it is not quite clear in what sense he employs this term.

VII. *Spurious and Incipient Cleavages.*

In a paper read before the British Association in 1857, Dr. Sorby[1] put forward what may be regarded as a limitation of his original theory of slaty cleavage. He showed that besides the structure contemplated in his earlier papers, which is 'quite independent of any actual fractures or breaks of continuity, and may be called *ultimate-structure*-cleavage,' there is also 'a cleavage due to very close joints, often so close as to be quite undistinguishable unless a thin section is examined with the microscope, whilst the arrangement of the particles in the spaces between them is independent of the direction of the joints, and is often related to quite another plane. This kind of cleavage may therefore be called *close-joints*-cleavage. The distinction thus enforced is abundantly confirmed by the microscopic study of various slate-rocks, and we shall therefore find it convenient to use the term *cleavage* in a sufficiently wide sense to include not only the structure we have discussed above under the name *slaty cleavage proper*, but also other structures, which, though effectively identical with it, have arisen in a different manner.

In fact Professor Heim, in his comprehensive work 'Ueber den Mechanismus der Gebirgsbildung,'[2] distinguishes three types of cleavage, which, however, may, and frequently do, occur in conjunction:

(i.) Cleavage produced by a succession of displacements or minute faults, resulting from small contortions; this he calls *Ausweichungsclivage.*

(ii.) Cleavage produced by the individual particles of the rock being flattened or elongated perpendicularly to the direction of maximum pressure; this is *Mikroclivage.*

(iii.) Cleavage produced by a parallel arrangement of all the flat and elongated constituents of the rock; to complete the terminology this might appropriately be styled *Fluidaltexturclivage.*

This last type of cleavage is that originally described by Dr. Sorby; the *Mikroclivage*, characteristic of limestones and similar rigid rocks, is that more particularly emphasised by Mr. Sharpe; while the *Ausweichungsclivage* is the structure, or rather the set of allied structures, which we have now to discuss, and which includes the 'close-joint-cleavage' mentioned above. It includes also those structures in which parallel planes of weakness (not actual discontinuity) occur in a rock at certain finite distances apart. If there be actual surfaces of disruption, there may or may not be appreciable displacement along them; the former case presents a series of minute reversed faults of very steep hade. They are, of course, 'close,' as distinguished from open joints, and they may subsequently become sealed up, either by mere cementation or by actual foliation taking place along them. If they thus become obsolete as surfaces of weakness in the rock, there may even be produced by subsequent changes a second cleavage cutting across the first, a result which we have seen to be impossible with true slaty cleavage.

Ausweichungsclivage assumes locally many curious forms, and these structures are met with on very various scales of magnitude, being sometimes very minute, at other times readily detected by the naked eye, when

[1] 'On Some Facts connected with Slaty Cleavage,' *Brit. Assoc. Rep.*, 1857, Trans. Sect. p. 92. Cf. President's Address to Geological Society, 1880, 'On the Structure and Origin of Non-Calcareous Stratified Rocks,' *Quart. Journ. Geol. Soc.*, vol. xxxvi. p. 72.

[2] Band ii. s. 49–58 (1878).

the term 'cleavage' ceases to be properly applicable to them. The same laws of formation seem to govern the small and the great. Professor Heim in his figure[1] illustrating the passage of an overfold into an overfault by the obliteration of the middle limb gives the scale as '$\frac{200}{1}$ to $\frac{1}{10000}$ of the natural size.' Some of the *macro*-structures analogous to this type of cleavage may therefore be found worthy of note.

First, however, it may be remarked that that flattening and elongation of the individual particles of the rock, which constitutes *Mikroclivage*, has its counterpart in the similar distortion of fossils, nodules, and pebbles; and where pebbles or other fragments of visible dimensions make up the bulk of a rock which has yielded uniformly under pressure, we have, in the flattened pebbles &c., a representation on a large scale of the micro-structure of slate as pictured by Mr. Sharpe. A cleaved conglomerate of this kind was long ago noticed by Professor Ramsay[2] at Llyn Padarn. It consists of 'slaty pebbles in a slaty matrix.' A similar rock, in which both pebbles and matrix are apparently compacted volcanic ash, occurred to me in the Boulder-clay at Nantlle. In this specimen the closely-packed pebbles are all strongly distorted in the same directions into approximately ellipsoidal forms. They are all very nearly of the same shape, the ratios of the axes of the ellipsoid being about 1·6 : 1·0 : 0·23, which figures are very nearly the same as those for the green spots in the slates of the district. Numerous examples of distorted pebbles in conglomerates occur in the eastern states of America;[3] the remarkable squeezed conglomerates of the Bergen peninsula have been well described by M. H. H. Reusch.[4] In such cases the pebbles are either so closely packed as to be in contact with one another or, as in the case of the Welsh conglomerates, the pebbles and matrix are about equally hard, and so yielded equally to pressure.

Another type of what we may call *macro*-cleavage corresponds to the structure produced by the parallel flakes of mica in the Llanberis slates; the difference being that in this case the flakes are less minute, and have had an original arrangement parallel to the laminæ of stratification. The laminæ are thrown into a series of small contortions in such a manner that the flakes of mica lie chiefly along certain definite parallel planes oblique to the general direction of stratification, which thus become planes of easy fracture or 'cleavage.' This kind of structure forms a connecting link with *Ausweichungsclivage*, to which type, indeed, it is referred by M. Reusch,[5] who gives a good example from the black, micaceous clay-slates of the Bergen district. In his figure the pseudo-cleavage-planes appear to be about $\frac{1}{8}$-inch apart, and this interval is determined by the scale of the small contortions.

As an example of true *Ausweichungsclivage* arising from minute and regular contortions, I may instance a black slate-rock from the pass of Drws-y-Coed, near Snowdon. In this rock the contortion has taken

[1] *Op. cit.* Atlas, Taf. xv., fig. 14.

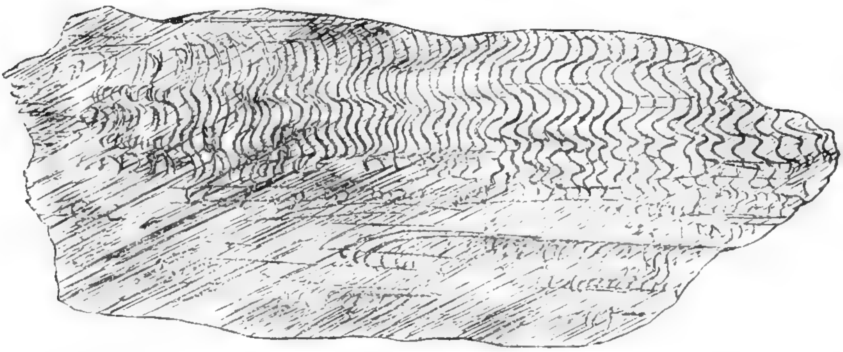
[5] *Op. cit.*, S. 51, fig. 32.

place in a more symmetrical manner than in the last-named, so that the resulting 'cleavage-planes' are perpendicular to the general direction of stratification. The interval between them is from $\frac{1}{8}$ to $\frac{1}{4}$-inch (fig. 11), but there is also some tendency in the intermediate parts of the rock to

FIG. 11.



× $\frac{1}{2}$.

split in the same direction. This is explained by a microscopic examination, which reveals that, besides the contortions mentioned, there is also a system of much smaller contortions, which give rise in like manner to a set of less pronounced cleavage-planes at distances of from $\frac{1}{50}$ to $\frac{1}{100}$-inch apart (fig. 12). If the rock be split along the bedding, which is easily done, these microscopic contortions are seen as fine striæ marked on the surface of the larger flutings, and having the same direction. The larger contortions in this rock, and the resulting 'cleavage' may be compared with an example figured by Professor Heim.[1]

FIG. 12.

× 25.

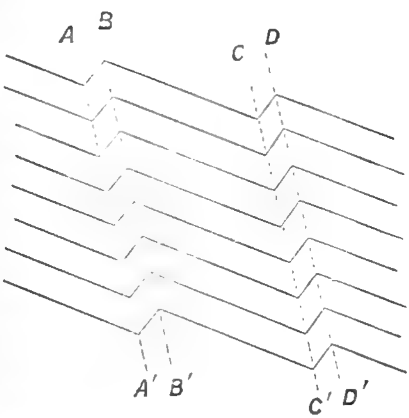
When a rock-mass becomes contorted by the action of pressure, it usually yields in such a manner that the contortions into which the planes of stratification, or any pre-existing planes, are thrown, are of an undulating form. It seems, however, that, under certain circumstances, zigzag, instead of undulating, contortions are produced, the crests and troughs of the contortions being not curved but more or less sharply angled, as in fig. 13. Here a shearing motion has taken place in the direction parallel to AA′ and BB′, but such shearing has occurred only in certain parts of the mass, such as those between AA′ and BB′, or between CC′ and DD′, while the other parts, such as those between BB′ and CC′, have not been affected. In the kind of contortions considered,[2] each zigzag is usually unsymmetrical, having a long and a short limb. Excellent

[1] *Op. cit.*, Atlas, Taf. xv., fig. 11.
[2] Cf. Stapff, *Neu. Jahrb. für Min., &c.*, 1882, Bd. i. S. 75.

examples, associated also with curved and irregular contortions, are met with in what Professor T. McK. Hughes[1] calls the 'gnarling' of the perplexing beds about Amlwch in the North of Anglesey. Some of these are figured in the Survey Memoir on North Wales.[2] In this case, if, as Professor Ramsay supposes, the planes such as AA′ in fig. 14 indicate the original stratification of the rocks, and the zigzag planes represent an obsolete cleavage, the shearing has taken place along the bedding, and has affected certain beds to the exclusion of others. Professor Liversidge[3] has described and figured a slate-rock in which the undoubted cleavage-planes are thrown into well-defined acute zigzags by subsequent contortion.

To return to *Ausweichungsclivage*, it is evident that planes like AA′ and BB′ in fig. 14, passing through the angles of the zigzag contortions, must be planes of structural weakness in the rock, even though no actual disruption of the laminæ of stratification may have occurred at the places where they are sharply bent. M. W. C. Brögger[4] states that such planes of weakness, which he terms *Knickungsebene*, are common in the friable, finely laminated beds of his Silurian Etage 2 in the Christiania district. I have noticed a dark shale at Porthwen on the north coast of Anglesey, in which the laminæ of stratification, marked by graptolites, are thrown into sharply defined zigzag contortions, the longer and shorter limbs of which are about 2 inches and $\frac{1}{4}$-inch respectively, in length. A similar instance is figured by M. Reusch[5] from Döbeln in Saxony. These rocks are readily fractured along the *Knickungsebene*.

Fig. 13.



Lastly, there is the variety of *Ausweichungsclivage*, in which the 'cleavage-planes' are actual surfaces of discontinuity in the rock—in fact, minute faults. Prof. Heim regards the faulting in this case as a further stage of unsymmetrical contortion of the laminæ of bedding, so that the dislocations are of the kind which he names *fold-faults* (*Faltenverwerfungen*), as distinguished from the ordinary *fissure-faults* (*Spaltenverwerfungen*). Examples on a microscopic scale are not uncommon: the 'gnarled beds' of Amlwch[6] afford a beautiful instance (fig. 14). As seen in the figure, the faults are related to the visible contortions of the rock, being roughly parallel to the axial planes of the zigzags or contortions (the apex of one of which is shown in the figure), but curving away upon reaching a felspathic layer, through which they do not pass. It is indeed evident that the faults could not be perpendicular to the direction of the lateral pressure which produced them. In accordance with what might

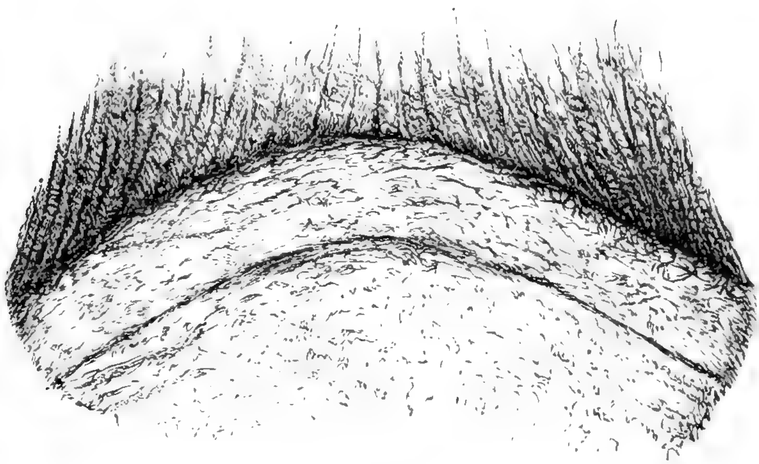
[5] *Op. cit.* S. 52.
[6] [Some slides of the Amlwch rocks show very clearly the passage of an 'overfold' into a 'fold-fault,' as described by Heim.]

be expected, the hade of the faults, measured from the axial plane, becomes less as we approach that plane, and the throw of the faults diminishes also. These faults are on an average about $\frac{1}{350}$-inch apart; a cleavage-structure on a like scale, and showing altogether very similar appearances, has been figured by Prof. Heim.[1] Owing to subsequent actions, the Amlwch rock shows no marked tendency to split in the direction determined by this microscopic faulting, but on examining one of the contorted surfaces of 'foliation,' the traces of the minute faults are visible as a very fine striation running parallel to the strike of the contortions.

Dr. Sorby,[2] in his Presidential Address to the Geological Society in 1880, described and figured an interesting case of cleavage due to close parallel planes of discontinuity in slate-rock at Liskeard, the planes being apparently about $\frac{1}{300}$-inch apart. This instance is instructive, because in the less disturbed parts of the same rock, where the cleavage is very imperfect, the earliest stage of the structure is seen in the shape of minute

FIG. 14.



×25.

contortions of the laminæ of stratification. He also pointed out that in some other cases, such as the pencil-rock of Shap, the effect of lateral pressure has apparently been to break up the laminæ of deposition in an irregular manner, so that the laminated structure is almost obliterated, and the microscopic flakes of mica, which constitute nearly the whole mass of the rock mentioned, are practically inclined about equally in all directions. This removed a difficulty which had previously been felt with regard to his original theory of slaty cleavage, viz., the postulate that the rocks which now form roofing slate had, prior to their becoming cleaved by lateral compression, &c., a structure in which the flat constituent particles were not arranged in laminæ of deposition, as is commonly the case in uncleaved shales, &c., but distributed at random in all positions. Dr. Sorby[3] had formerly endeavoured to account for this assumed original structure of slate-rock by the supposition that the microscopic flakes of mica in it were of secondary origin; but we now see that the required arrangement might be brought about by the earlier effects of

[1] *Op. cit.*, Taf. xv., fig. 8. [2] *Quart. Journ. Geol. Soc.*, vol. xxxvi. Proc. p. 73.
[3] *Brit. Assoc. Rep.*, 1857, Trans. Sect. p. 92.

the same lateral pressure which, as a final result, produced the cleavage structure in the manner described in preceding sections. This supplementary hypothesis therefore must be regarded as an essential part of the mechanical theory of slaty cleavage.

It appears from the above remarks that a system of close parallel planes of discontinuity in a rock, though lacking many of the characteristics of slaty cleavage proper, may be in general effect very similar to it; and, again, that such a structure may be itself a first step towards the true slaty cleavage. Such planes of discontinuity, however, are not properly speaking joints, but rather small faults. They are due to lateral pressure, and their distance apart is determined by the dimensions of the small folds which are a first step towards the faulting. True joints, on the other hand, although, as in the case of the 'cleat' of coal, they may be very close together, must be ascribed proximately to lateral tension, and their distance apart seems to be regulated by the lithological character of the rocks in which they occur,[1] and doubtless also by the thickness of the beds which they traverse.

If, however, a rock having originally a true jointed structure be subsequently subjected to lateral pressure, it may fairly be supposed that this pre-existing jointing will affect the results of the pressure. Thus, unless the direction of the pressure be nearly perpendicular to the joints, the rock may conceivably begin to yield by sliding along the joint-planes, which thus become small reversed faults, and the subsequent effects of the pressure on the rock may be modified accordingly. This point is emphasised by Professor W. King,[2] who, however, makes it the starting-point of a general theory of slaty cleavage, in which he will probably have few followers. Stated in his own words, his thesis is that 'Slaty cleavage is essentially the result of pressure exerted against divisional planes, chiefly belonging to jointing, that existed in any given rock prior to its becoming affected by such pressure.' But there seems to be no evidence to show that jointing or any other special structure is a necessary preliminary to cleavage, and it is yet to be proved that the direction of the cleavage-planes produced in a rock by lateral pressure is in any way dependent on those pre-existing planes of weakness, which we should naturally expect would be obliterated as such by the action of the pressure itself.

In connection with the subject of jointing, it may be noted that many of the recorded instances of a second direction of cleavage in rocks are due to a confusion between cleavage and fine lamellar jointing.[3]

VIII. *Comparison of the Cleavage- and Fluxion-structures.*

We shall find it convenient to use the term *fluxion-* or *flow-structure*[4] in a wide sense, to embrace all those structures, whether macroscopic or

microscopic, consequent upon a flowing motion of a mass of any material. The comparison between slaty cleavage and the various types of fluxion-structure met with in different rocks has been made by Mr. Poulett Scrope and others.[1] The movement which the parts of a rock experience under the action of the forces which produce slaty cleavage may evidently be regarded in the light of a flowing motion along the cleavage-planes in the direction of their dip, and so is analogous to the similar flowing of other plastic materials, such, for instance, as a viscous lava.[2] Thus the rearrangement of the ultimate fragments of a slate-rock in the general direction of the 'grain' or cleavage-dip corresponds to the arrangement of the microlites in a rhyolitic or andesitic lava parallel to the lines of flow: the distortion of fossils, &c., in the slate is analogous to the drawing out of vesicular cavities in the lava into amygdaloidal or ellipsoidal forms: the more resisting fossils, around which the cleavage is slightly curved, are paralleled by the porphyritic crystals in the lava, round which the lines of flow sweep in curves: and, finally, both the fossils in a cleaved rock and the porphyritic crystals in a lava are occasionally found to be shattered and the fragments drawn apart in the direction of flow. Fluxion structure, in its various phases, is moreover common, though local, in plutonic, as well as volcanic rocks; and where a rock is largely made up of parallel tabular or linear crystals of such minerals as felspar, &c., it is not infrequently found to possess in consequence a kind of rude macro-cleavage, either lamellar or fibrous, in the direction so determined.

This 'parallel-structure,' to be clearly distinguished from foliation on the one hand and from platy jointing on the other, was long ago remarked by various geologists;[3] the 'grain' in certain Cornish granites, described by Professor Sedgwick[4] is a structure of this character. In rocks which have a large proportion of isotropic ground-mass, the fluxion-structure does not produce any marked tendency to split parallel to it.

Hitherto we have spoken of the flowing of igneous rocks only when in a partially molten condition; but the comparison may be carried much further. Since the experimental researches of M. Tresca[5] the flowing of solid bodies is no longer a contradiction in terms, and of recent years the plasticity of rock-masses has been the subject of much discussion.[6] In greatly disturbed regions even the hardest rocks are found to have suffered a mechanical deformation, which is in part of the nature of

flowing. In describing the phenomena in the neighbourhood of the great 'thrust-planes' of Eriboll, the officers of the Geological Survey [1] repeatedly make use of the expression 'fluxion-structure' as one specially applicable to the result of a shearing motion in the rocks. According to the character of the rocks affected and the intensity of the forces to which they have been subjected, the deformation of the mass appears to have proceeded partly by internal fracture and faulting of the rocks, and partly by their gradual and continuous distortion in the manner of plastic bodies. In fact, continuous and disruptive movements seem to have taken place concurrently, in such a way that the planes of shearing with the consequent 'grain' or fluxion-structure are not always distinguished from planes of abrupt slipping with their associated slickensides. A characteristic of these intense mechanical changes is that they are frequently accompanied, and their results complicated, by the paragenesis, recrystallisation or destruction of some of the constituent minerals of the rocks and the production of new ones. In this way foliation and gneissic structure may be produced as the result, partly of mechanical, partly of mineralogical and chemical agencies. Apart from these last, however, the plastic movement or flow, which in a crystalline rock gives rise to foliation, is precisely analogous to that which in a clastic rock produces slaty cleavage; and in fact where rocks of the required lithological types are found associated together and affected by the same movements, the foliation of the one passes into the cleavage of the other. As, moreover, the development of new minerals takes place on the cleavage-planes of the latter as well as on the foliation-planes of the former, it is impossible to draw any line of demarcation between the two structures. As instances of foliation associated with, and in part at least produced by, mechanically caused movements, we may cite the hornblende-schists of the Bergen peninsula and the Saxon Erzgebirge, and the granulites, and probably in part the gneisses of the latter region. An instance on a small scale has been described by Mr. Teall in a dyke at Scourie, Sutherland, where the conversion of dolerite into hornblende-schist is clearly exhibited.

By regarding cleavage and some cases of foliation in the light of fluxional structures, we gain a clue to some of the difficulties connected with those phenomena. The segregation of the several constituents into lenticular patches is a peculiarity of some types of foliation, and, indeed, in some gneisses, presents a very characteristic appearance. Now it is a matter of common observation that a 'stream of liquid moving in any general direction tends to divide itself, more or less, into veins and threads composed of particles of different degrees of coarseness, and, consequently, of different degrees of mobility, and moving at different rates.' The significance of this was pointed out by Mr. Poulett Scrope [2] in connection with his theory which made the foliation of gneiss and mica-schist an original structure produced during the protrusion of an igneous mass in a partially molten state, and the same principle would probably have at least a limited application to the flow of solid rock masses which gives rise to the foliation or fluxion structure in the Eastern gneiss of Sutherland and other rocks of like character. Whether the segregation in these cases is to be referred in any measure to the cause described, or whether it is

due solely to the action of molecular forces, which would probably be intensified by the extreme pressure, is one of the questions which must be left for further elucidation.[1] But as bearing upon this question, and as showing that it is a speculation by no means foreign to the subject of slaty cleavage proper, we may notice the interesting case described and figured by Professor Bonney,[2] of a 'structure imitative of foliation produced by pressure on a stratified rock without important mineral change.' Here, in a cliff section at Torcross, South Devon, are alternate layers of fine dark mud and silt, the former predominating, which are much folded, and consequently inclined at various angles to the cleavage which traverses the whole. Where the cleavage and bedding coincide, the layers, though much compressed, are distinct; but where the angle between the direction of pressure and the normal to the surface of the bed has been a large one, the stripe is obscured or obliterated, and a new structure produced. The broader gritty bands have their edges 'frayed out,' or send out comb-like processes into the finer bands in the direction of the cleavage; the narrower bands are entirely obliterated and replaced by a new structure of parallel lenticular streaks or elongated 'eyes' extending in the direction of the cleavage.

Connected with the tendency of a heterogeneous mass in flowing motion to separate into layers or patches is its liability to unsteady or sinuous motion. The very tortuous fluxion structure exhibited by many rocks of volcanic origin must be ascribed to this circumstance. As Mr. Poulett Scrope[3] remarked with reference to the ribboned and banded trachytes, &c., the contortions are owing to 'the various degrees of mobility of the different layers, those of coarser grain . . . retarding the motion of the proximate layers which possessed a greater liquidity.' In fact, the resistance to motion within a moving mass of the kind considered would be more of the nature of surface friction than of viscosity, and so would be a condition unfavourable to steady motion.[4] A similar explanation may apply to those cases in which contorted foliation is attendant upon the fluxional motion of rock masses.[5] Such contortions occur, it should be noticed, both along the dip and along the strike of the foliation.

The constant association of intense mechanical deformation and crushing of rocks with molecular and atomic changes of a certain character naturally leads to the inquiry, what is the nature of their connection, and to what extent can the two phenomena be supposed to have a common origin? In fact, in what measure the intense lateral pressure which we assume to have been the agent by which a fluxional structure was impressed upon solid rock masses, may be held to account for concomitant changes of a mineralogical and chemical kind. Some materials for such an inquiry will find their place in the following section.

But to prevent misconception, I must point out at this stage, that in the present paper, foliation, except in so far as it is related to cleavage, has no proper place. Our subject embraces only those types of structure

which are clearly referable, in whole or in part, to the action of mechanical forces. With the views of those geologists who ascribe the formation of certain schists to unique physical conditions prevailing in Pre-Cambrian times, we are in no wise concerned. Neither is it within the province of this paper to discuss superinduced foliation on pre-existing structural planes in a rock. We will only remark that such foliation in a stratified rock may apparently be produced upon any kind of structural planes previously existent in the rock, whether of lamination, bedding, current-bedding, cleavage, or jointing; and that the foliation will follow whichever of these sets of planes is the most pronounced, according to Forbes's law of 'least resistance.' Further, such superinduced foliation may apparently be formed upon structural planes in a crystalline rock. Referring to the central portion of the Alps, Professor Bonney[1] says: 'The gneissic mass has been crushed, cleaved, and on the cleavage planes films of a hydro-mica have been developed. We cannot fail to be struck, when once our eyes have been opened to it, by the frequency of a slabby structure in the more central parts of the Alpine ranges, the surfaces of these slabs being coated with minute scales or films of mica.' These he regards as 'records of a rude cleavage which has been impressed upon the more central and less flexible portions of the Alps during the great earth-movements which they have undergone since they were first metamorphosed.'

IX. *Physical and Chemical Changes dependent on Pressure.*

A simple pressure acting at any point of a mass in a definite direction is mathematically equivalent, as may readily be proved,[2] to (i.) a uniform pressure in all directions, combined with (ii.) certain shearing stresses. The former tends to produce a compression of volume without change of shape, the latter a deformation without alteration of volume. It is then to the latter that the mechanical deformation or fluxion of rock-masses must be attributed; while the former, which is of the nature of a hydrostatic pressure, may prove to have been at least an important factor, if not indeed the prime agent, in the mineralogical and chemical changes observable in the same rocks. We shall therefore, to fix ideas, disregard for the present the shearing stress and the consequent movements of the rock, and consider only that 'quaquaversal' or uniform pressure with which hydrostatical theories render us familiar.

The importance of pressure as an element in the conditions of molecular and chemical changes has from an early date been more or less clearly recognised by geologists as well as physicists. It figures, at least as an accessory, in all modern theories of 'regional metamorphism,' and high pressures play an important part in the experiments of those who have worked at the artificial production of minerals and the imitation of the structures of crystalline schists.

Pressure, however, does not appear to be always ranked in its proper place as a condition, coördinate with temperature, determining the action of all physical and chemical forces; and its importance as such does not seem to be thoroughly realised in the discussion of all geological questions. Indeed we may say with Professor Lehmann[3] that 'we stand at present

[1] *Proc. Roy. Inst.*, vol. xi. p. 64 (1885).

only on the threshold of a knowledge of the changes of substances and their effects upon one another under the influence of pressure.' Among those whose experimental researches have added to our knowledge in this line may be mentioned Sir James Hall,[1] Sir William Thomson,[2] Sir D. Brewster,[3] Dr. H. C. Sorby,[4] M. L. Cailletet,[5] Dr. F. Pfaff,[6] and M. Walth. Spring.[7]

Speaking generally, it may be said that the effect of increased pressure is to facilitate such physical and chemical changes as involve a contraction of volume in the substances operated upon, and to retard changes which are accompanied by an expansion. For instance, both theory[8] and experiment[9] show that the melting-point of a solid is raised or lowered by an increase of pressure, according as the substance expands or contracts in melting. Again, the experiments of Dr. Sorby prove that when a salt contracts on passing into solution, which is the case with most known substances, the effect of augmented pressure is to increase its solubility. This fact he has shown[10] to have important bearings in geology, for it follows that where a mass of rock is subjected to unequal pressure, some of the constituents may be dissolved at those points where the pressure is greatest, and redeposited where it is least. In a contorted limestone band among slate-rocks at Ilfracombe, the calcareous matter is seen to have been thus removed from the central portions of the limbs of the folds and collected at their crests and troughs, which suggests another possible explanation for some cases of the obliteration of stratification by pressure and its replacement by lenticular and elongated structures. In a Devonian limestone, too, the stems of encrinites have been partially dissolved on those sides where they were subjected to the greatest pressure, and the crystalline calcite redeposited on those sides where the pressure was least; this observation is of importance in connection with the effects of intense mechanical forces upon the individual crystals and crystalline grains of a rock, which might thus change their form by molecular rearrangement without possessing in themselves the property of plasticity[11] in any degree.

Next, it has been recognised since the classical experiments of Sir

James Hall, that pressure exerts a modifying influence on the passage of bodies from the amorphous to the crystalline state; the experiments of M. Spring[1] go to establish the law that this change is assisted by increased pressure, when the volume of the substance diminishes in the process of crystallisation.[2] The same observer has shown that substances of almost every kind in the state of powder can be welded into a solid mass by the action of very great pressure without high temperature.

More striking is the effect of pressure upon chemical changes. Dr. Sorby,[3] in 1863, suggested a direct correlation between mechanical and chemical forces, but M. Spring, using much higher pressures, obtained results of a very definite character. He found, for example, that by operating upon a mixture of sulphur and copper filings, with a pressure of 5,000 atmospheres, he obtained crystallised copper sulphide. He laid down the rule that pressure assists those chemical changes which involve a diminution of bulk. The complementary part of this law, that pressure retards or prevents such chemical actions as are accompanied by an increase of bulk, had already been supported by the experiments of M. Cailletet and Dr. Pfaff.

Such facts as the above seem to afford a firm basis for a mechanical theory of metamorphism, applicable to regions which, by their general structure, present evidence of the action of great pressure, but not to be applied to any given district without inquiry into the epoch of the chemical and mineral changes in the rocks, and the possible existence of other metamorphosing agents. For a comprehensive study of a difficult tract of metamorphic rocks from a purely mechanical standpoint we may go to Dr. Lehmann's work on the 'Saxon Granulitgebirge,' referred to above.

Viewing the matter in the most general way, we may start from the axiom that both physical and chemical forces are controlled by two conditions—temperature and pressure. Wherever we see evidence of changes in rock-masses other than those now in progress among surface rocks, we may infer the operation of either extreme temperature or excessive pressure, or both these conditions in conjunction, and the decision must depend on a full consideration of the facts. Experiment shows that in certain cases of physical and chemical changes, elevated temperature and increased pressure tend in the same direction, while in others they conflict. In the latter case, had we sufficient data, we should obtain a crucial test as to which of the two agencies has been answerable for the changes in question; but for this purpose we must await further evidence from the laboratory. It may, however, be safely affirmed that some of the mineral changes evinced in the districts we have mentioned cannot credibly be referred to the effects of high temperatures, and are even the reverse of those changes which we know to be ordinarily produced by heat. For instance, the conversion of augite and diallage into hornblende is a fact witnessed to by several observers;[4] but at ordinary pressures fused hornblende recrystallises in the form of augite.[5] The

[1] *Loc. cit.*

[2] As an example of this principle, compare a holocrystalline with a vitreous rock of similar chemical composition; the former, produced under great pressure, is *denser* than the latter, which consolidated at an ordinarily low pressure.

formation of white mica and quartz by the destruction of orthoclase is probably another significant metamorphosis; muscovite, like hornblende, has never been reproduced artificially. The mode of occurrence of hydrous micas, frequently associated with slickensides and other immediate evidences of stress, seems to point to the importance of mechanical forces in their genesis. Professor Bonney[1] considers that 'these filmy minerals appear to be very readily formed under pressure from damp argillaceous material in a state of fine division,' and is of opinion that 'perhaps it is hardly too much to say that the difference between a satiny slate or phyllite and an ordinary shale is due even more to the action of pressure than to mineral composition or geological age.' The same authority, however, insists on an essential distinction between such rocks and true schists, which latter, he maintains, require for their production something more than mechanical forces.

In weighing the relative importance of the results of mechanical stress on the one hand, and the more direct effects of the central heat of the earth on the other, it must not be overlooked that not only increased pressure, but also rise of temperature may result from the former agency. 'The heat produced locally within the crust of the earth by transformation into heat of the mechanical work of compression, or of crushing of portions of that crust,' as in Mr. Mallet's[2] experiments, has been invoked by Professor Prestwich,[3] in a recent paper, as a factor of the first importance in the metamorphism of certain regions, such as the Appalachian Mountains and the Ardennes. This transformation of the mechanical work done by pressure into heat is, of course, quite distinct from the *direct* effects of pressure on physical and chemical forces discussed above. The latter necessitates no rise of temperature, but involves an immediate correlation between mechanical work and the energy of molecular and atomic forces.[4] The heat in the former case, moreover, would arise partly from the hydrostatic pressure and consequent compression, partly from the shearing stress and associated deformation; and in hard rocks the latter would doubtless be of the most importance. It seems reasonable to suppose, then, that the work done upon a rock by a lateral pressure to which it yields is expended in three ways—viz., in producing deformation of the rock mass both by plastic shearing and by fracture, in bringing about molecular and chemical changes in its composition, and in generating heat, which will again give rise to changes not always of the same kind as the former. The proportion of the available energy devoted to each of these effects must naturally depend upon the nature of the rocks operated upon.

Considerations such as these may perhaps serve in some measure to lessen the difficulties that beset the study of cleavage and foliation by referring apparent anomalies to the different lithological characters of the rocks affected. Thus in Mr. Teall's[5] dolerite dyke molecular rearrangement is seemingly an earlier effect of the forces concerned than foliation-structure, while, in Professor Bonney's Torcross section, the reverse is the case. In an originally soft rock, a deformation or flowing, with its

attendant phenomena, would doubtless be the first effect of lateral pressure, while a more intense application of stress might induce mineral changes of the nature already alluded to. Thus it may, according to some speculators, be possible to bridge over the differences between schists and gneisses of certain types, on the one hand, and satiny slates or phyllites on the other, while between the latter and ordinary slates every gradation may be found.

In this way we arrive at Dr. Darwin's[1] theory that 'in most cases foliation and cleavage are parts of the same process; in cleavage there being only an incipient separation of the constituent minerals; in foliation a much more complete separation and crystallisation;' or, again,[2] 'that the same power which has impressed on the slate its fissile structure or cleavage has tended to modify its mineralogical character in parallel planes.' This may be compared with the hypothesis of Mr. W. Hopkins,[3] that slaty cleavage is the result of molecular forces, but has its direction determined by mechanical stress. Dr. Darwin apparently supposed that the mechanical force was not only a directing influence, but also the prime cause of the molecular actions. In so far as this is a return to the purely crystalline theory of slaty cleavage, as advocated by Professor Sedgwick, the mass of evidence referred to in the preceding sections must compel us to pass it over; but we may reconcile Dr. Darwin's valuable observations with the theories of Dr. Sorby and others, by admitting that many of the rocks which we call slate have experienced a development of new minerals (such as micas, chlorites, and epidotes) concurrently with the production in them of the cleavage structure, and that there appears to be a passage from such rocks into mica-schist and foliated gneiss. In fact, it seems probable that if the term cleavage be applied only to rocks in which no mineral changes are to be detected, the class of cleaved rocks will be much reduced in size; and, further, that if we ascribe all such mineral changes in slates to subsequent foliation on cleavage planes, the number of our metamorphic regions will be greatly augmented. In North Wales, for instance, Professor Sedgwick[4] described the cleavage planes of the slate as 'coated over with chlorite and semicrystalline matter, which not only merely define the planes in question, but strike in parallel flakes through the whole mass of the rock.' From the microscopic examination of the same rocks, Dr. Sorby[5] regarded the minute scales of mica which make up a large part of the mass, and resemble in structure 'pseudomorphs of mica or chlorite after felspar' as being of secondary origin; and although he apparently considered the origin of these scales anterior to the cleavage structure, he stated that these so-called clay slates are 'analogous to very fine-grained mica-schist, into which they gradually pass by the increase in the size of the crystals of mica.' In the roofing slates of other districts there is often evidence of mineral changes which appear to have been contemporary with the cleavage.

In leaving this part of the subject, we may remark that certain other theories, not otherwise of much interest, have linked together cleavage and foliation under a common explanation. Professor H. D. Rogers,[6]

endorsing with modification Professor Sedgwick's crystalline theory, held that 'both cleavage and foliation are due to the parallel transmission of planes or waves of heat, awakening the molecular forces and determining their direction,' a view differing from that of Dr. Darwin only in that it assigns the part of pressure to heat. A similar idea with respect to cleavage had been expressed by Sir John Herschel.[1]

X. *The Relation of Cleavage to Earth-movements.*

The theories discussed in the foregoing pages make the cleavage of rocks a result of lateral thrust operating throughout larger or smaller tracts of country, and the extreme stages of the structure, which involve mineralogical as well as lithological changes, a consequence of the intense stresses in the earth's crust[2] to which mountain-systems owe their structure. Into the ultimate cause of these mechanical forces we are not called upon to enter;[3] but some of the resulting peculiarities in the arrangement of cleavage planes over an extended area require a passing notice.

As regards the strike of cleavage, its regularity over considerable distances[4] and its parallelism to the main axes of disturbance of the district in which it occurs, need not be further dilated upon; local exceptions to the latter rule have been noticed by various observers. As regards the cleavage-dip, no such simple laws can be laid down. The angle of dip may have any value, though the most perfect cleavage is usually inclined at a high angle. So far as observation at any one locality can discover, the dip of the cleavage is quite independent of that of the bedding. On traversing a district of slate-rocks in the direction across the cleavage the dip is observed to change very slowly and gradually; when an abrupt variation is noticed there is reason to suspect some disturbance posterior to the production of the cleavage-structure.[5] In fact, subsequent tilting and faulting of the rocks may affect not only the dip but to some extent also the direction of strike of the planes of cleavage; and wherever in the preceding pages we have referred to the cleavage-strike and cleavage-dip, the *original* strike and dip of the cleavage-planes ought strictly to be understood. As another possible source of error in observing the dip of cleavage-planes must be noticed the not infrequent surface-curvature[6] of those planes in consequence of movements of the rocks near the surface of the ground, a phenomenon well seen in the valleys about Snowdon.

Dr. Charles Darwin,[7] who made careful observations of cleavage and foliation over a large part of the South American coast, suggested as an explanation of the varying and opposite dips that the cleavage-surfaces—though to the eye appearing plane—may possibly be 'parts of large abrupt curves with their summits cut off and worn down.' Mr. Sharpe,[8] following out this line, endeavoured to trace out 'systems of cleavage' in

Wales, Cornwall, and Devon, and the Cumbrian Mountains,[1] and subsequently in the Scottish Highlands.[2] He maintained that in each of the districts, which he regarded as distinct areas, there are certain lines of strike, many miles apart, along which the cleavage is vertical; that on each side of such a line the cleavage dips towards it, and at continually lower angles, until midway between two such lines is a zone of horizontal cleavage; so that over such an intermediate place the cleavage-surfaces, if carried on continuously, would pass in broad flat arches. With such an arrangement, low angles of cleavage-dip would be much more prevalent than they are found to be. Professor Phillips criticised Mr. Sharpe's theory and some of the sections on which it was based, and even these sections themselves only bear out the author's view in a very limited degree. It is curious, too, that M. Laugel[3] employed Mr. Sharpe's data to verify his own quite different theory of a sheaf-like or fan-like arrangement of the cleavage-planes of a district, which is much more in agreement with recorded observations. According to Mr. Sharpe[4] this appearance is due to the junction of two of his arches, but certainly the prevailing high dips in most districts where cleavage is well developed point to the fan-like arrangement as the essential part of the phenomena. This latter peculiarity is specially characteristic of mountain systems, where, as noted by Dr. Darwin,[5] the cleavage-planes on the flanks of the mountains 'frequently dip at a high angle inwards.' In a symmetrical mountain complex also there is usually a parallelism between the cleavage-planes and the axial planes of the folds into which the strata are thrown, as remarked by Professor H. D. Rogers.[6] In less disturbed districts the fan arrangement is less perfect, and any connection between the direction of the cleavage-planes and the position of the folds of the rocks is, as a rule, not to be made out except occasionally on a small scale.[7] A traverse through the slate-districts of North Wales seems to show that the cleavage-planes, as it were, oscillate from one side of the vertical to the other when followed in a direction perpendicular to their strike, as if there were a series of imperfect fans; some of the Geological Survey's sections show the same character.

Mr. Sharpe's presumed arch-arrangement was used by him to support an *elevation theory* of cleavage, which was briefly that a mass of fluid igneous matter, forced upward through a fissure coinciding in direction with the axis of the 'area of elevation,' had compressed the surrounding rocks; the pressure being supposed to act radially, the resulting cleavage-planes, which are at right angles to the direction of pressure, would form a flat arch. The fan-arrangement, on the other hand, seems to connect itself in a simple manner with the *lateral compression theory*;[8] for a mountain mass thus elevated would be acted on by lateral thrust somewhat like that in an arch of brickwork; the cleavage-planes, being perpendicular to the thrust at each point, would be arranged like the planes which separate successive bricks in the arch, i.e. in a radiating or fan-like manner.

The last point we have to refer to is one of some importance, as raising a possible objection to the mechanical theory of cleavage: it is the relation in point of time between the earth-movements and the production of the cleavage-structure. It has been pointed out by Professor Sedgwick,[1] Professor Phillips,[2] Mr. Sharpe,[3] and others, that the cleavage appears to have been impressed on the rocks subsequently to their being thrown into synclinal and anticlinal folds by the disturbing forces. Mr. Fisher,[4] insisting on this view, maintains that 'cleavage is due to an internal movement of the rocks rendered necessary by the disturbed region being left, after elevation, in a position too lofty for equilibrium.' This theory, it will be noticed, ascribes the elevation of the area in question to forces acting directly from below upwards. I have endeavoured elsewhere [5] to show that the kind of movement advocated by Mr. Fisher would result in an arrangement of the cleavage-planes and a difference in the perfection of the structure in different parts of the area, which is quite out of accordance with the facts.

It is evident that the cleavage-planes would be affected by so much of the disturbance of the rocks as was subsequent to their formation, and consequently the cleavage-structure, at least in its final state, must have been of later origin than the foldings by which it is not disturbed. Professor Tyndall [6] seems to be of opinion that the production of the cleavage was more or less simultaneous with the disturbance, and consequently has been actually affected in a certain measure by the displacement of the rocks in which it occurs. At least this is apparently implied in his explanation, quoted above, of the deviations experienced by cleavage-planes in traversing alternating strata; this phenomenon admits, however, as we have seen, of a different explanation. It may be remarked too, that the fan-like arrangement which often characterises cleavage-planes in a district of disturbed strata might be connected with a certain amount of elevation in the central parts of the area subsequently to the setting up of the cleavage structure. But this does not in any way touch the fact that in any ordinary slate district the planes of cleavage may be seen ranging with approximate parallelism through contorted beds, the irregularities of which do not in any way affect the former. From this we cannot but infer that the impression of the cleavage structure on the rocks is an event of later date, in the main, than the tilting and flexures observable in them.

Granting this, however, we are still able to regard the cleavage and the folding as concomitant, though not simultaneous, effects of the same lateral pressure. As has been remarked by Mr. Fisher himself, they are two distinct ways of satisfying the same lateral compression of an area. But as the cleavage involves a rearrangement of the intimate parts of the rocks and an actual compression of their bulk, we might naturally expect it to be a later result of the lateral pressure than those changes which merely consist in displacement of the rock-masses as a whole. This consideration may fairly be held to remove the difficulty alluded to in accepting the theory which refers the origin of cleavage to the same mechanical stresses that brought about the disturbed position of the strata.

On the Strength of Telegraph Poles.

By W. H. PREECE, *F.R.S., M.Inst.C.E.*

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

THE resistance of timber to rupture has frequently been experimentally investigated both at home and abroad, but almost invariably with the view of determining the dimensions or scantling of beams, trusses, and framed structures. Few experiments have been made upon naturally grown trees with a view of utilising them in their native condition.

Fincham's [1] experiments on the relative qualities of timber used for the masts of ships were made upon cut pieces, 4 feet in length, and 3 square inches in sectional area. The strength of square balks was investigated by Messrs. Tredgold, Barlow, and others, the results giving a constant of 1,341 for red pine in the formula

$$w = \mathrm{K}\,\frac{bd^2}{l} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where $w =$ breaking weight in lbs. at end of beam.
$b =$ breadth in inches
$d =$ depth ,,
$l =$ length ,,
$\mathrm{K} =$ a constant dependent on the character of the timber.

The formula for round timber based on the same value of the constant K becomes

$$w = \mathrm{K}\,\frac{4{\cdot}7r^3}{l} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

r being the radius.

The value of the constant quoted above was obtained by experiments on small sections of timber one and two inches square only. Wisely distrusting results obtained in this manner, Mr. Edwin Clark, during the construction of the Britannia tubular bridge, caused trials to be made with beams of red pine 12 inches square, which gave a constant of 810 only, whilst experiments on balks of Baltic fir made by the Mersey Dock Board gave results varying between 771 and 873. Mr. Gavey, during certain investigations made in Bristol in 1876, obtained a constant of 804 from square sections cut out of Norway round telegraph poles.

Telegraph poles in England now consist principally of native grown unhewn Norwegian or Swedish red fir preserved with creosote.

They have acquired their pre-eminence by a species of natural selection, after extended trials of cut Memel timber, native grown larch, and preserved Scotch fir. The Scandinavian red fir is now almost exclusively employed. It seems to have been provided by nature specially for telegraphic purposes.

[1] *Papers on Naval Architecture*, vol. i. pp. 53–4.

The specifications for telegraph poles, in addition to quoting dimensions, prescribe that they are to be winter felled, sound and hard grown (*i.e.*, well-hearted, with the annual rings closely pitched), straight, free from large or dead knots and other defects, to have the bark completely removed, and to contain the natural butt of the tree. They are usually from 5 to 6 inches in diameter at the top, and they grow with a taper that accords satisfactorily with the theoretical law that should give the greatest strength at each section of their length.

No systematic inquiry has, as far as I am aware, been made into the mechanical properties of Scandinavian red fir in its native or unhewn state, though at different times isolated experiments have been made on its resistance to flexure.

The immense growth of the telegraph system in this country, the increased utilisation of public highways with their bends and curves, the wind pressures arising from the rapid multiplication of wires, have forced closer attention to the stresses applied, and to the more scientific bearing of the question. The selection of the proper scantling has been very much a rule of thumb process, but stability has been obtained by struts, stays, and double poles framed together. Subsequent experiments have, however, shown that practical experience has not erred in specifying dimensions.

As considerable doubt existed as to whether constants obtained from square timber could be accurately applied in calculating the strength of naturally grown trees, in which the annual rings of growth were unsevered, it was determined by the Post Office authorities to make careful and accurate measurements of the strength of the poles actually used, and a substantial testing apparatus was constructed for the purpose. A stout wrought-iron cylinder, 14 inches in diameter and 6 feet long, was rigidly held down on a suitable framing by two 2-inch tie rods. The butt of the pole to be tested was placed inside this cylinder to a depth of 5 feet 6 inches, carefully packed all round, and tightly rammed with gravel to represent the conditions when in use. It was then placed horizontally, a scale pan was suspended from what would be the resultant point of a line of wires at the further end of the pole, and weights were added until the pole broke. An oak plank or saddle distributed the load as would be the case on an actual line of telegraph.

Table No. I. contains the results of the experiments made upon ten comparatively newly creosoted poles.

This gives a mean constant with formula 2 of 1,337, that obtained from the seven stout poles alone being 1,302, and from the three light poles 1,417.

As the investigation referred primarily to lines built with stout poles, 1,302 is the value used in calculating subsequent tables.

Table No. II. contains the results of similar experiments made upon six old poles creosoted fifteen years ago, and upon three uncreosoted poles imported in 1884, the constants being 1,276 and 1,232 respectively.

As previously stated, formula 2 is really derived from experiments made on square timber, a multiplier being used to reduce results when round timber is in question. But obviously the strength of round timber varies as the cube of the diameter, so a constant has been obtained for the formula

$$w = K \frac{D^3}{l} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

D being the diameter;
whilst for poles of elliptical section it becomes

$$w = K \frac{D^2 \times D_1}{l} \quad . \quad . \quad . \quad . \quad . \quad . \quad (4)$$

D being the axis in the line of stress, and D_1 that at right angles to it.

The value of K, for formulæ 3 and 4, as deduced from the mean of the experiments on new stout creosoted poles, is 765.

It appears from these experiments that creosoting does not impair the strength of red fir, and age has had no apparent influence on its qualities.

The curves formed by the poles in bending were very perfect. Rupture invariably took place at the ground line, and about half broke by fracture of the upper fibres under tension, while the other half buckled in the under fibres under compression, showing that nature had proportioned them well to their work.

An important question that arises out of this inquiry is what shall be the proper scantling of timber and the span separating the poles on telegraph lines of varying number of wires.

In solving this problem we have not only to take into consideration the proper factor of safety to be allowed, and the wind pressure to be exerted upon the wires and the poles, but the fact that the diminution of spans beyond certain limits is impracticable owing to the injurious lowering of the insulation by the multiplication of supports.

The factor of safety is 4, and the maximum wind pressure per square foot is taken at 18·75 lbs., reducing the effective area in the ratio of ten to six, owing to the circular section of the wires. We know very little of the average pressure on a long wire supported close to the ground. Most records have been made in exposed positions, and at considerable heights, whereas the average height of a trunk line of wires is but 20 feet above the surface. The President of this Section (Mr. Baker) thinks 30 lbs. per square foot a fair average to take for telegraph wires when very much exposed, but considering the frictional resistance of the ground and the obstructions due to hedges, banks, walls, trees, &c., I am inclined to consider this too high for low levels. We have usually taken 18·75 lb. per square foot as a fair measure of the wind pressure on our wires, and the results of practice very much confirm this view.

Table No. III. has been drawn up showing the strength of round poles one foot long, and varying in diameter from 6 to $13\frac{3}{4}$ inches. To obtain the strength of any pole it is only necessary to divide the tabulated breaking strain by the length of the pole in feet.

The strength of the timber being satisfactorily settled, and a maximum wind pressure and factor of safety having been accepted, the length of spans for varying lines is readily calculated. Tables IV. and V. give the stresses on seventeen and twenty wire lines, so arranged as to fulfil the implied conditions.

The experiments and calculations in this paper were done by Mr. Andrew Bell and Mr. John Gavey, of the Post Office Telegraph Department.

On the Use of Index Numbers in the Investigation of Trade Statistics. *By* Stephen Bourne, *F.S.S.*

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

Whatever opinions may be held on the oft-mooted question whether statistics are to be deemed a science or merely as an art, there can be no denying that statistical research may, and ought to be conducted on scientific principles. The collation of facts, the method in which they are grouped and treated, and the results attained by such treatment, is as truly the pursuit of science as is the study of many another branch of knowledge directed to the discovery and promulgation of truth. Many of the elements with which statisticians have to deal are obscure and variable, but the conclusions they may be made to support are capable of being of as definite establishment as those worked out by the processes of the more exact sciences. One of the methods resorted to is the use of an 'index number,' which as its name denotes, indicates certain conditions and connections of figures which it is otherwise difficult to associate with each other. The use of this method is not without difficulty, and two or three instances in which it has been adopted may serve to illustrate both its merits and its disadvantages, as well as an introduction to the special occasion for its application which forms the subject of this paper.

The late Professor Jevons, in a pamphlet on the fall in the value of gold published in 1863, sought in this manner to indicate the various changes which had taken place in the price of the various articles of commerce following upon the then recent gold discoveries in Australia, and from thence to infer that the altered nominal values were in reality due to a depreciation in the value of the precious metal in which these prices were expressed. Later on, the same evidence of a fall in price was adduced in proof of the subsequent appreciation of gold, which more recently both Mr. Goschen and Mr. Giffen have asserted to be still in progress. Collecting together the average mean prices of thirty-nine different commodities during the six years of 1845–50, the Professor took these as the *datum* line with which to compare those of the three years 1860–2. Subsequently adding to these seventy-nine new commodities, and by logarithmetic calculations dividing the arithmetical averages of the former period into that of the later three years, he obtained a ratio or percentage which represented the rise of prices presumed to be due to the fall of gold. Having thus reduced prices expressed in various coins—pence, shillings, and pounds—and appertaining to quantities denoted by various weights, measures, and numbers, to a series of index numbers each having a definite and proper relation to the commodity it represented, it became possible to add together the equivalents of that which could not be otherwise combined, and so to obtain an average marking a distinct alteration with respect to gold. This was taken to establish a universal rise in price corresponding to a depreciation of gold by about 9 per cent., which was thereby deemed to be proved to have taken place.

The 'Economist,' commencing with the average price for the same six years, 1845–50, of each of twenty-two separate articles or groups of

articles, to which it gave the index number of 100, has year by year calculated for a new index number the percentage of variation in price and thus indicated the specific yearly rise or fall down to the present time. Thus cotton wool, the price of which was represented at the commencement of the series by 100, the actual price being $8\frac{1}{4}d.$ per lb., rising to $10\frac{3}{8}d.$ in 1873, was represented by 126, the result of $\frac{10\frac{3}{8}\times 100}{8\frac{1}{4}}$. In the interval it had risen in 1866 to the equivalent of 267, and in 1883 fell so low as 71. It is evident that $\frac{126+267+71}{3}=154\frac{2}{3}$, or leaving out from each the original 100, $\frac{26+167-29}{3}=54\frac{2}{3}$ would give the index numbers for the average price or increase of price for those three years, and by conversion back into pence show the actual price and increased price: for as $100 : 154\frac{2}{3} :: 8\frac{1}{4} : 12\frac{3}{4}$ and $100 : 54\cdot\dot{6} :: 8\cdot25 : 4\cdot51$, and so on for every succeeding year. Each of the twenty-two articles being on the datum line as 100, the total index number becomes 2,200, and the several new numbers in the following years being added together, we get 3,564 and 2,947 as the totals for 1866 and 1873, with 1,364 and 747 as the respective indications of the general rise in prices. The index for 1st January, 1885, is but 2,098, showing, so far as this table is evidence, that we have now reached the lowest prices for at least thirty-five years.

This table however—good as it is so far as it goes—is defective, inasmuch as it only deals with the quotations for forty-four distinct articles out of the numerous commodities in which we deal, and it takes no account of the relative importance of the articles, either in the range of value, or the quantities bought and sold. Thus wheat at 30*s.* to 50*s.* per quarter, of which we grow some 80,000,000 bushels, and import some 120,000,000 more, reckons for no more than indigo at 2*s.* to 8*s.* per lb., the transactions in which must be limited to the 100,000 cwts. we import. Again, including as it does four descriptions of cotton, each numbering as one out of twenty-two, the unusual fluctuations to which this article is subject affects the index number, for the years in which this may occur, in a fourfold degree. The same to less extent may be said of iron. These sources of derangement, together with that of the entire omission of such an important article as coal, led me, in a paper on the silver question read before the Statistical Society in 1879,[1] to substitute corrected index numbers in which these two sources of error were avoided. The effect of these corrections was to reduce amongst others the average index number of 1865 from 162 to 138, and to increase that of 1873 from 134 to 142. It is obvious also, as the 'Economist' itself remarks, 'that in the course of so long a period of years, 1845–84, some variations have inevitably arisen in the mode of quoting prices.'

It must be evident therefore that imperfections in the data upon which these calculations are made prevent entire confidence in their results, notwithstanding the scientific accuracy in the methods employed. It is probable, however, that for the purpose of comparing one year with another or others, especially with those not separated by long intervals, the ratio of progress is accurate. In such statistics as these, which embrace a multitude of small items, and thus afford opportunities for minor errors to balance each other, the results are not far from the truth, even

[1] 'Some Phases of the Silver Question.' *Stat. Journal*, vol. xliii.

though the figures for one or other period may not be absolutely correct. Since each one is liable to the same chances of error, the relative accuracy may thus be quite sufficient for purposes of comparison.

The most recent instance of the use of index numbers is perhaps that contained in this year's report upon 'Changes in Imports and Exports,' rendered by Mr. Robert Giffen to the Secretary for the Board of Trade. The object here sought for is to ascertain the yearly progress of the nation's trade with colonies and countries outside its own borders, both as regards its money value and the volume of the goods which it receives and parts with. This, so far as the value is concerned, is easily ascertained by the figures published year by year in the 'Statistical Abstract,' which sets forth the value of each principal article of both import and export, with the combined value of all the minor articles, and then collects them all into one total which shows in one sum the aggregate import, and in another, that of export. Thus we find without any calculation that in 1883, the last year with which the paper deals, the imports were valued at 427,000,000*l.*, whereas ten years ago they were at 371,000,000*l.*, showing an increase of 56,000,000*l.* Also that the values of the exports at the same dates were 240,000,000*l.* and 255,000,000*l.*, the difference being 15,000,000*l.* against the later period. In like manner that the sum total at one time was 667,000,000*l.*, and at the other 626,000,000*l.* Also that the imports exceeded the exports in 1883 by 187,000,000*l.*, and in 1873 by 116,000,000*l.* These particulars are by no means all that are needed for the formation of a true judgment as to our trading prosperity or adversity. To the banker or the broker it may be sufficient to know the gross amount on which commissions may have been earned or charges realised; but the merchant needs to understand the changes in the goods which have passed through his hands, the shipowner has to take note of the quantity of goods he has carried. So the economist looks to be informed of the volume of our trade, and it is the business of the statistician to evolve from such data as are within his reach the fullest information they are capable of furnishing. This is not so easy as at first sight it appears to be.

The 'Statistical Abstract,' the only source of information dealt with on the present occasion, sets forth the principal articles in quantity where that is capable of expression, and the respective values for each enumerated article, all others being included in one total of value only. If the investigation be confined to one article alone, little more than inspection is needed. Take for instance pig iron, of which we exported in 1883, 1,564,000 tons, at a value of 4,077,000*l.*, and in 1873, 1,142,000 tons, at 7,118,000*l.*; and cotton yarn 265,000,000 lbs., at 13,500,000*l.* in the one year, and 215,000,000 lbs., at 15,895,000*l.* in the other. There is no difficulty in seeing wherein the quantities and values have in each case changed, but inasmuch as the quantity of one is stated in tons and the other in pounds weight, and the unit values are in pounds and in pence, we cannot as with the money add the two together, to see whether on the whole the bulk has increased and in what proportion. Much less could all the goods having the quantities in yards, gallons, &c., be thus brought into one representative sum. Mr. Giffen therefore takes 100 as the index number for the total value, say of exports in 1883, which we have seen to be 240,000,000*l.* Then to find the proportion of the pig iron value, says, as 240,000,000 : 4,077,000 :: 100 : 1·7, the index number for pig iron; and as 240,000,000 : 13,500,000 :: 100 : 5·6, the

index number for cotton yarn. Pursuing the same course with each of the other articles of export for that year, which are enumerated in quantity as well as value, and adding them all together, he arrives at a total of 61 as the index number of the whole, which stands as the index number or representative of 146,000,000*l.* out of 240,000,000*l.* In like manner dealing with any other year, say 1873, he takes 100 to represent its total value of 255,000,000*l.*, and finds the index number of the enumerated articles to be 67·2. It should be observed here that the index number for 1883 is $\frac{61}{100}$ of 240,000,000*l.*, and that for 1873, $\frac{67\cdot2}{100}$ of 255,000,000*l.*, so that the two index numbers do not stand in a definite relation to each other. This is a defect, as I venture to think it, to which allusion will be made further on. Thus far the process has been with values only, and the index numbers show no more than the actual money figures do. The use to be made of them is to get other index numbers that shall represent quantities also, and so determine whether, and to what extent, the volume as well as the value of one year has changed with reference to the other. This is effected by the following means. In the first place, a simple division of the total value by the total quantity of each article in each year will show the average price per unit whether that be a ton, pound, yard, gallon, or any other measure.

Keeping for illustration to the two articles already quoted, it appears that $\frac{4,077,456l.}{1,564,048\text{ tons}}$ gives 52·14*s.* as the price per ton of pig iron in 1883, and $\frac{7,118,037l.}{1,142,065} = 124\cdot65s.$ the price for 1873, giving a decrease of 72·51*s.*, which shows that this article was more costly by 139 per cent. in the earlier than the later year. So with cotton yarns $\frac{13,509,732l.}{264,772,000} = 12\cdot25d.$, and $\frac{15,895,440l.}{214,778,827} = 17\cdot76d.$, from whence it is seen that this article was 45 per cent. higher in price in 1873 than in 1883. If now, we increase the index numbers of 1883 by 139 and 45 per cent. respectively, we get $\frac{1\cdot7 \times 139}{100} = 2\cdot36$, and $\frac{5\cdot6 \times 45}{100} = 2\cdot52$ as additions which will represent the alterations necessary when quantity is considered as well as value.

Mr. Giffen, however, has preferred a comparison with 1861, and to take the proportion of each article as it was in 1875 instead of that of each year, and has worked out the alterations thus to be made for twenty of the years included in the period 1840–1873. Taking then the total index number ascertained for 1875 to be 65·8, he finds that 1873 is + 19·93, whilst 1883 is − 5·95; that is (though he does not so state it), these changes would make that for 1883, compared with 1873, as 59·85 to 85·73, in which proportion the values of the latter year must be increased to bring them into comparison with the former. Thus 146,000,000*l.* must be increased to 209,000,000*l.*; and assuming that the non-enumerated articles vary in the same ratio $224,000,000l. \times \frac{85\cdot73}{59\cdot88} = 321,000,000l.$, as the value to which the total exports of 1883 would have reached had the prices been the same as in 1873.

Adhering to the principle of the foregoing calculations, there would

yet appear to be room for simplifying and improving upon them. In the first place it seems erroneous for the purpose of comparing one year with another or others, that the component parts from which the yearly index numbers are built up, or rather we should say into which each of them is split up, should not have a common basis to rest upon, so that they may be added to or subtracted from each other, and then converted back into the figures of actual values, as for instance, cotton yarn in 1865 is 6·2 per cent. of 166,000,000*l.*, in 1883 5·6 of 240,000,000*l.*, and therefore cannot be combined without previous reduction to a common denominator. It is proposed therefore to reduce all to one standard, and to choose 240 millions, the total exports of 1883, for the datum amount. This too because in the latter year a greater number of articles are specifically enumerated, and we can in consequence operate upon a larger proportion of the whole. It is evident that whether we take 1, 10, 100, or 1,000 as the standard index, the figures into which it is divided will be the same, only differing in the place of the decimal point. In the Board of Trade tables 100 is chosen, which for closeness of calculation requires the use of decimals, and also of the plus and minus signs, whereas if 1,000 be taken we avoid the use of both, and all our indices are in whole numbers. Thus the total value of enumerated articles in the tables, which is expressed by 61·0, or by adding 9·4 for articles not included in the enumeration of earlier years, will appear as 704, which is the same thing without the point. But that for 1840 will be 214 instead of 79·1. Hence $\frac{704}{1000}$ and $\frac{214}{1000}$ can be added together or otherwise dealt with, because the denominator signifies the same amount, but $\frac{70{\cdot}4}{100}$ and $\frac{79{\cdot}1}{100}$ cannot be, because the 100 stands in one case for 240 and in the other for 51 millions. The one set of tables will show at a glance the proportion which exists between every figure they contain, which the other requires an elaborate calculation to discover.

The object to be attained, as already pointed out, is to get a number which shall indicate for each article, and for the whole together, the bulk as well as the value, and so to ascertain the very important point, whether the changes, both in the respective items and the grand total, are due wholly, or in what proportion, to an increased or diminished volume of goods, or to a variation in the prices at which they are valued. Hence it is convenient to make 1883 the year for comparison, rather than 1861, which Mr. Giffen uses, and this once established may be utilised for succeeding years, until some great alteration in the conditions of trade may make it necessary to adopt some new method of exhibiting its effects.

The number of distinct articles which are specified, both as to value and quantity, is 65, for each of which individual calculation has to be made in each year. These furnish a wide enough range for assuming with safety that those which cannot, for want of definite information as to quantities, be so estimated, may be taken in the same ratio of bulk as the others are found to yield. The mode of estimation is first to convert the value for each given year into a number proportionate to that of 1,000, which is the index number for 1883. Then taking the price per unit, be it a pound, a gallon, or a yard, as deduced from the amounts and shown in the 'Statistical Abstract,' to consider that for 1883 as 1·00, and for other years in the percentage of increase or decrease. Having thus obtained a divider for the value index, the resulting number becomes

an index of quantity for each article, and so by simple addition for the whole of the specified articles in each year. To illustrate this process, in 1883 the exports of cotton yarn were in round numbers 265,000,000 lbs., and the value 13,500,000*l*., in 1865 they were 103,500,000 lbs. weight, and 10,300,000*l*.; the price per lb. being 12·25*d*. and 23·98*d*. respectively, or 96 per cent. higher in the earlier year. The value index of 56 stands for 1883, but being multiplied by 1·96 we change it into 110 to represent the value 26,400,000*l*. which would have accrued had the price been the same as in 1865. Or reversing the process we divide 42, the index for 1865, by 1·96, giving 21·5, to show the value 5,165,000*l*. which the yarn of that year would have realised had it been sold in 1883, and thus get the ratio of quantity to value for this article. All the enumerated goods being dealt with in the same way, and the non-enumerated assumed to follow the same ratio, it is evident that the index numbers fairly indicate the proportionate bulk of the trade in the respective years. The following tables in which the enumerated articles, instead of being separately detailed, are gathered into groups, show first (A) certain index numbers for 1883, and the changes which would have to be made on estimating the goods at the prices of three other years within the decade 1873–83, and of one earlier year 1865, in which the disturbance of prices arising from the American Civil War exercised a marked influence upon the export trade of this country. Secondly (B), the index numbers for these same four years are shown in parallel columns with the alterations that the prices of 1883 would have produced. These illustrate the manner in which the full set of tables for a series of years may be easily used to manifest the fluctuations in quantity as well as value, either by way of comparison between later and earlier or earlier and later years.

A.—*Exports of* 1883 *in Index Numbers, together with those numbers as they would have been at the prices of other years.* 1,000 = 240,000,000*l*.

The index number of 1,000 that has been employed to represent the 240,000,000*l.* of British produce and manufactures exported in 1883, and to which all the other numbers have the same relation, might have been applied to the value of 1884, and would have been so done but that the 'Statistical Abstract' for last year was not published in time. The figures required could be gathered from other sources, but not in quite the arrangement of their component parts which fits them for the comparison that will be made when the 'Abstract' makes its appearance.[1] So large an index number has been used for convenience in calculating the very numerous items depending upon it, but it is obvious that by cutting off the three ciphers and prefixing or inserting the decimal point in other places, we shall have the relation of all the other figures to the value of

[1] *Vide* end of paper, pp. 872–3.

1883 as the unit. We have then for the last twelve years, 1884–73, the following actual values and their respective index numbers:—

	£	Index No.
1884	232,927,575	·971
1883	239,799,473	1·000
1882	241,467,162	1·006
1881	234,022,678	·975
1880	223,060,446	·929
1879	191,531,758	·798
1878	192,848,914	·803
1877	198,893,065	·829
1876	200,639,204	·835
1875	223,465,963	·931
1874	239,558,121	·998
1873	255,164,603	1·063
Average	222,781,583	·928

Stating also the values of 1865 and 1864 we get a comparison with two years of high prices though not of large exports. In

1865	£165,835,725	Index No. ·692
1864	£160,449,053	„ ·669

But this Index may also stand for the collected quantities of the goods exported in 1883, and then represents the x or unknown gallons, yards, cwts., &c. of the various articles, whether detailed or not in the trade figures; and as already shown it may be split up into its component parts. Altering each one of these according to the variation of the prices of other years and collecting them into one total, we get a comparison between the bulk which the index of money in the standard one 1883 bears to that of other years, for it needs no explanation to show that a given amount of money represents a greater or lesser quantity of goods according as the prices of these were lesser or greater. Thus (A) taking the index number of 1883, as standing for both money and quantity, and altering it for each of the four years given by way of illustration in the foregoing table, we get a number which enables us to estimate the growth in bulk at present as compared with the past. Or (B) taking the index number for each of those years as standing for quantity and money alike, and altering it to the standard of prices in 1883, we ascertain what proportion quantities in those years bear to the later one.

A. At prices of former years	1883 Index No. 1·	B. At prices of 1883. Index No. 1·		
in 1879 would have swollen to	1·006	·798 would have shrunk to	·798	= 1 to 1
1875 „ „	1·277	·931 „ „	·739	= 1 to ·794
1873 „ „	1·463	1·063 „ „	·727	= 1 to ·684
1865 „ „	1·497	·692 „ „	·460	= 1 to ·665.

The one set of figures indicating the enlarged volume of goods the money of 1883 would represent as compared with its predecessors, the other the contracted bulk of those previous years as compared with 1883.

One more comparison is needed to show the full bearing of these numbers. The actual difference betwixt the values of the trade of one or more years and other years is thus compounded of two elements, the one arising from differing quantities, the other from varying prices. The foregoing increases to the index numbers of 1883 do not indicate the additions to the value of our trade, but only what would have resulted

from a maintenance of the prices obtained in former years. They in every case exceed the actual differences between the index numbers, and consequently the money value of the several years, which being deducted from the apparent increase which represents the bulk, the remainder will show the diminution in the value of this branch of our trade in 1883 from that of the other quoted years. This will be made more distinctly apparent by disregarding the use of the index numbers and showing the sums which they represent. In the following table, column (A) is the total value of the exports in the years previously noted; (B) the excess or deficiency of the figures of 1883 over or below those amounts; (C) the additional sums which would have accrued in 1883 had each former year's prices remained; and (D) the consequent net remunerative advantage or disadvantage to our whole export trade in 1883, as compared with the four earlier and one subsequent year, regard being had to both quantity and price.—

	A Million £	B 1883 + or −	C 1883 + or −	D
1883	239·80			
1879	191·53	+ 48·27	− 2·	+ 46·
1875	223·47	+ 16·33	− 66·	− 50·
1873	255·16	− 15·36	− 111·	− 127·
1865	165·84	+ 73·96	− 119·	− 46·
1884 with 83	232·93	− 6·87	+ 10·	+ 3·

Prior to the publication by the Board of Trade in 1879 of its first report, to which that already referred to relating to the trade of 1883 is a successor, the 'Economist' compiled tables arriving at much the same results by an independent method. In these, without resorting to an index number, the value of the goods of the later year was directly calculated at the prices of the former, to show how much the bulk would have realised had there been no change of price, the difference being the gain or loss from having obtained higher or lower prices. Thus the difference between these computed sums and the actual values manifested the gain or loss due to greater or smaller quantities. These tables have been continued from year to year, and being drawn from the figures of the monthly trade account published seven days after the last day of each month, the readers of that paper have before them, within a month after the termination of each year, a pretty accurate comparison with the trade of its predecessor in imports as well as exports. Calculations for exports on the same plan between 1883 and 1873, and dealing with articles represented in the later year by 166,000,000*l.*, showed that the prices of the earlier one would have given 83,000,000*l.* more than they realised, and the actual difference in the values of the two years, 23,000,000*l.*, was thus shown to give 60,000,000*l.* as the loss from diminished value lessened by the increase in volume. The value of the non-enumerated goods being assumed to have followed the same course will give results agreeing with index number method, and so confirm the accuracy of both.

Similar figures, to be found in that paper for 31st January last, are for the present used in the foregoing tables to show that whereas the exports for 1884 were valued at 232,928,000*l.*, as against those of 1883, the gain

from increased sales of 2,733,000*l.* was lessened by 9,604,000*l.* from lower prices, the actual difference adverse to last year being 6,871,898*l.*

Of the present year, only two-thirds having elapsed, it is impossible to speak definitely, but assuming that the next four months will follow the same course as those which are gone, it is probable that there will be a further decay of 21,000,000*l.* on the total of last year. Of this a rough calculation points to one-third as the probable loss from quantity, and two-thirds the failure in prices.

Although the purport of this paper has been to explain the method of investigation rather than the results to be obtained by its use, it would scarcely be right to leave wholly untouched some of the evidence it elicits, or the problems whose existence may thus be manifested, though not solved. Had time permitted, illustrations might have been drawn from the import records which admit of exactly the same treatment that has been bestowed upon the exports. Before this, however, it may be well to allude again to the differences of the two methods as accounting for the figures evolved by the one process differing from those produced by the other.

It has been previously noticed that the selection by Mr. Giffen of 1861 as a basis narrows the list of articles which can be specifically calculated by so many as were not enumerated in that year, and so throws the calculation on the whole year to be made upon a smaller proportion. In 1883, 61· instead of 70·4, leaving 39· to be averaged instead of 29·6. But it does more than this, for many of the classes left out in the later year are really included in the earlier. For instance, the total value of iron exported in 1861 was 10,000,000*l.*, and in 1883, 29,000,000*l.*, but only 6·4 represented the latter, whilst 5·6 stood for the former in building up the index numbers, owing to the exclusion of descriptions separately shown in 1883, but included under more general heads in 1861. This applies still more to earlier years.

Then the choosing for the index number a percentage of the actual value of its own year, instead of some fixed datum, rendered the figures of unequal values in the different years. Thus 61, the index for 1883, meant $\frac{61}{100}$ of 240,000,000 = 146,000,000*l.*, whilst 71·1, for 1861, meant $\frac{71 \cdot 1}{100}$ of 125,000,000 = 89,000,000*l.*, each unit of the index being of double value in one year to what it bore in the other.

Again, taking the proportions of 1875 as those to which the increased prices should be reckoned as affecting the index of all years alike, could only be correct for such years as happened to have the same relative quantities as in that particular year, and must be particularly injurious where a very high or low price happened to be coincident with a greatly varying quantity. This too would be aggravated or minimised by the proportions being those of value rather than of quantity. Thus the proportions of cotton yarn for 1865, 1875, 1883 stood as 104 : 216 : 265, but by value as 10 : 13 : 14, and the percentages of increase or decrease from the standard of 1861 were as + 91·23 : + 41·63 : − 2·31. It is difficult to see how any combination of these factors, so widely differing in their ratios, can bring about the result that the index numbers for cotton yarn should be altered as +5·38 : +1·00 : − 0·14 as shown in the Board of Trade tables.

The effect of these three several arbitrary departures, as they seem to

be, from sound bases in the Board of Trade tables does not affect the total results so much as might be supposed, from the fact that the year 1875 on which the calculations are made was one unmarked by any great irregularity in any of the articles, either in quantity or price, and also from the deviations happening to take different directions, so as to neutralise each other. The effect of the two systems may be shown side by side for the five years already detailed in a previous table, where the alteration in the index numbers, and the export values they represent, were based upon the prices of 1883, thus:

	Prices of 1883			Prices of 1861	
	Actual Values	Index No.	Altered Value	Index No.	Altered Value
	£		£		£
1883	240,000,000	1,000	240,000,000	59·85	264,000,000
1879	192,000,000	798	192,000,000	59·70	212,000,000
1875	224,000,000	739	177,000,000	74·47	198,000,000
1873	255,000,000	727	174,000,000	85·73	196,000'000
1865	166,000,000	460	111,000,000	89·26	122,000,000

The prices of 1861 having been 10 per cent. higher than those of 1883 would make that difference between the calculated values in each of the years. These index numbers of 1861 will not however permit of being added together, either in the whole or the several parts, for the different articles, because they are in each year percentages of varying totals, whilst those for 1883 are in every case a percentage of the same amount, namely the total of that year, 240,000,000*l.*

But having got these altered values by applying the prices of one year to others and deducting from them the actual values of the respective years, it would appear in the case of the three years that the bulk of our trade in 1883 is to be measured as more than 1875 by 83,000,000*l.*, than 1873 by 96,000,000*l.*, and than 1865 by 193,000,000*l.* But both 1865 and 1873 are abnormal years in which the extravagant prices of coals, and therefore of iron, or of cotton, ran the total values up to an undue extent, and so by the large proportion they are of our whole trade had an unfair influence, not only upon the values of these goods themselves, but upon the average of the non-enumerated as well. For instance, the price of cotton in 1865 raised the index number in comparison with 1883 by adding 243 to 299, being 81 per cent., whereas all the other enumerated articles together only added 107 to 405, being 24 per cent. In like manner the cost of coals in 1873 added 54 to 44, at the rate of 123 per cent., and the other goods, excepting metals which were almost equally affected, were increased 309 on 521, or but 59 per cent. For the ultra free-trader therefore to compare the results of these two exceptional years, as has often been done, with 1883, is about as absurd as should some opponent of sanitary reform in Spain compare the death-rate of some future year, when cholera has ceased its ravages, in proof of the superior healthiness of the nation in the later over the previous year. The true worth of such investigations is historical, as furnishing one factor amongst the many which are combined in influencing the prosperity of trade, and sets of tables thus constructed may possibly be of great help in the collection of information towards solving the problems committed to the consideration of the recently appointed Royal Commission on Trade.

It is essential that one other warning be given. After all the care which can be exercised in eliminating sources of error, it is not at all certain that the quantities of goods, though expressed in the same denominations, are in truth alike in the substance of the unit. A ton of coals cannot vary in quantity, or greatly in quality, from year to year, but a yard of cotton piece goods may greatly alter in width, thickness, and fineness of texture, according to the make which happens to be saleable at the time. Fabrics of mixed materials, such as cotton or jute conjoined with wool or silk, do greatly change in the proportions of the dearer substance, as well as in size or texture, according to the fashion of the day. There is good reason to believe that in all these respects the yards of both cotton and woollen goods are now intrinsically less valuable than they were in past years, and in whatever degree this may be true of these and other goods, the comparison of goods by the price, weight, or measurement must be fallacious. As an instance of this, it happened that the value given for a consignment of shirtings to New Zealand was challenged as being preposterously low. The production of invoices proved the figures of both yards and money to be absolutely correct, and that the goods were really described as shirtings. But further inquiry elicited the fact that these goods were destined not to make shirts for Europeans, or even for Maories, but to form shrouds for the carcases of sheep in the refrigerating chambers of the vessels bringing them home. For this purpose a much inferior article was serviceable, although in the trade accounts it would necessarily be grouped with those of far higher quality and price.

But it is high time to leave these wearisome details and descriptions, and to point out a few of the purposes for which the tables may serve. They must be regarded as means, not ends; tools wherewith crude and unsightly statistics may be reduced into useful, and it may be comely shapes. Like interest tables and logarithmic numbers, though equally tedious to construct, and far more difficult to describe, they may save a vast amount of labour to those by whom they are used, and lead up to results of real utility.

In the first place, the extreme variation of price within short periods of time, and the equal irregularity of their recurrence, forbid the assumption that gold is now or has very lately been altering in value. I do not say that it may not have become appreciated, but if so the evidence to sustain the theory must be sought elsewhere. When coals rose from 8·84*s.* in 1863 to 20·49*s.* in 1873, and in 1883 sank to 9·20*s.* it cannot be affirmed that the change was in the metal rather than the mineral. Contrast this with cotton yarn, which in the three years named stood at 26·01*d.*, 17·76*d.*, and 12·25*d.* Like the gold itself, to procure which we must crush down the quartz in which it lies imbedded or wash away the sand with which it is mixed before the grains are discovered, so the hard mass of statistics, or the encumbering multitude of figures, must be ground or boiled down if we would eliminate the truth from the surrounding sources of error so prone to lead the judgment astray.

In the next place, by bringing out so clearly the great accessions to the bulk of our trade, and yet limiting these changes within narrower bounds than many economists are disposed to admit, we discover the severe fall which prices have sustained, and hence the enormous quantity of goods we have to give for an equal or lesser amount of money. Comparing 1883 with 1873, for instance, we find the actual value of the goods we sold to have been 15,000,000*l.* less, or a fall of 6 per cent., whereas

the goods given were at least 40 per cent. more. It is often claimed that this is but a temporary alteration, accompanied by conditions which neutralise the injury. No doubt in many cases there has been a contraction in the cost of the materials employed which, if imported from abroad, especially from foreign countries rather than our colonies, is a clear saving to the nation. Yet even this is not so when home capital is employed in their production abroad. But when, as with coals and iron, the whole proceeds of the sale are distributed at home, the diminution of these proceeds is a home loss. Improved mechanism or increased industry may have lessened the expenditure on production by diminishing or restraining from proportionate increase the numbers to be sustained out of these proceeds; and to this may be attributed the number of workers who are out of employ, or what is still more largely the case at present, the short time in which they are working. But it surely cannot be gravely maintained that there is here no depreciation in our most important means of obtaining wealth. Neither does an attentive consideration of these figures afford any assuring indication that the evil is in process of passing away. Again, we find that the decay in prices of imports is greatly below that of exports. Even Mr. Giffen's figures show that the index number by which the bulk of the trade is estimated—for the exports of 1865 has to be altered from 65·8 by the addition of 23·46, and for 1883 by the deduction of 5·95, a correction of 45 per cent., whilst that of imports has to be changed from 81·16 by an addition of 13·59 and deduction of 9·43, a correction of but 28 per cent.—the corresponding alteration in total value having been 47 and 36 respectively; that is, we have lost nearly twice as much by the reduced prices of our sales as we have gained by those of our purchases. It seems mockery to talk of enlarged trade as a proof of national prosperity when these are the terms on which it is conducted. But in truth the whole of this part of the question depends upon whether the prevailing lowness of prices is due to causes which are removable or temporary, or to such as are in process of increase and so likely to be enduring.

It is by no means to be presumed from what has been said that the consideration of these figures or the grave teachings they afford are in any way calculated to support a return to protection, or whatever is meant by 'fair' as opposed to free trade. The declension in prices and the consequent destruction of profits arise from the fierce competition to which our manufactures are exposed in the markets of the world, and especially in those countries which wield protection against us. These evils would be multiplied tenfold by any steps which would increase the cost of our home products for foreign sale. It is to the extension of the ground our markets cover, and to increased economy of production, that both manufacturer and artisan should look for the desired recovery from the prevailing depreciation of their products.

I fear that details and figures such as these have been difficult to follow without diagrams large enough to be seen, but trust that those who are accustomed to follow calculations of this sort will not think I have altogether failed in the attempt to put them upon a truly scientific basis.

The following table shows the method of arriving at the index numbers and of comparing one year with another. The index number for the

price of each article in 1883 is 1 or 100, according to the use or otherwise of the decimal point. The index for quantity is the same as that for value in the standard year (1883); that for 1884 is arrived at by dividing the value index by the price index, and is shown in the last column. The variations in prices between these two years are not sufficient to alter many of the smaller index numbers unless carried to one or two decimals. It will be seen, however, how few are the articles of which the quantity is large enough to have much influence upon the total result.

The Forth Bridge Works. *By* ANDREW S. BIGGART, *C.E.*

[PLATE VI.]

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

WORKS of exceptional magnitude, and more especially those in which the difficulties in the way of their accomplishment are in any degree proportionate to their size, must of necessity be of interest to this Association, constituted as it is to assist, and in its own way act as a beacon to all in search of true knowledge.

While the difficulties met with in preparing for and founding the piers

of the Forth Bridge have been neither few nor unimportant, it is patent, to even the uninitiated, that causes for anxiety will neither disappear nor diminish till the erection of the steel superstructure has been completed.

Presently my remarks will be confined to the main steel piers and approach viaducts. The term steel piers refers to those parts of the superstructure immediately over and between any of the three groups of four caissons. Described generally, each may be said to consist of two sloping and two vertical planes; the sloping, including one connecting horizontal column and two 12-foot rising columns, joined at the upper extremities by the top member, while from the lower end of each to the top of the opposite one there extends a diagonal eight-foot tube. These two planes run parallel with the centre line of the bridge, and are 120 feet apart at the base and 33 feet at the top.

The vertical planes complete the structure at the ends of the two sloping planes. They consist of the 12-foot rising columns, already mentioned, with the lattice bracing joining these together. These members, with the internal viaduct and the bracing girders attached to the skewbacks, form the principal parts of the steel piers, the extreme height of which is fully 340 feet above the bottom of the lower bedplates.

The approach viaducts are, generally speaking, of ordinary design, with the exception of some special features to meet the unusual requirements demanded of them. The girders span a distance of 160 feet, and rest on granite-faced piers, rising to a height of 130 feet above high water; the heights of these piers themselves gradually diminishing as they near the abutments, owing to the rising nature of the banks of the river.

The magnitude of the main steel piers, both in respect of their great height and immense weight, demands that exceptional means be employed in their erection. Many proposals for effecting this have been suggested, and may be said to range from that of Mr. Arrol's first, which was to run up the columns independently, using them as the only staging, to that proposed by Mr. Baker, viz., to carry up simultaneously with the columns a rising platform, extending round the whole four columns, by utilising them as supports, and upon this platform to carry up the top member, having the end junctions all previously riveted up, so that on arrival at the top the final closing lengths of the 12-foot rising columns had only to be joined to the junctions already fitted, to complete this part of the work. After careful consideration the weight requiring to be lifted was found to be too great, when compared with the advantages to be gained, to allow of its full adoption In the case of the Fife and Queensferry piers, the weight was close on 1,200 tons, and several hundred tons more in that of Inch Garvie.

A modification of this plan is that finally adopted by Mr. Arrol, with Sir John Fowler and Mr. Baker's full approval. The carrying up of the top member is done away with, but otherwise it is very similar.

The main lifting girders of the platform pass through the 12-foot rising columns, and running in line with the vertical planes extend from the one sloping plane to the other. Lying across these are placed other four girders, one being on either side of each set of 12-foot rising columns, thus completing a rectangular platform resting indirectly on the main rising columns. The weight of this platform, including the necessary cranes and other plant required during the erection of the higher parts of the pier, will be about 400 tons.

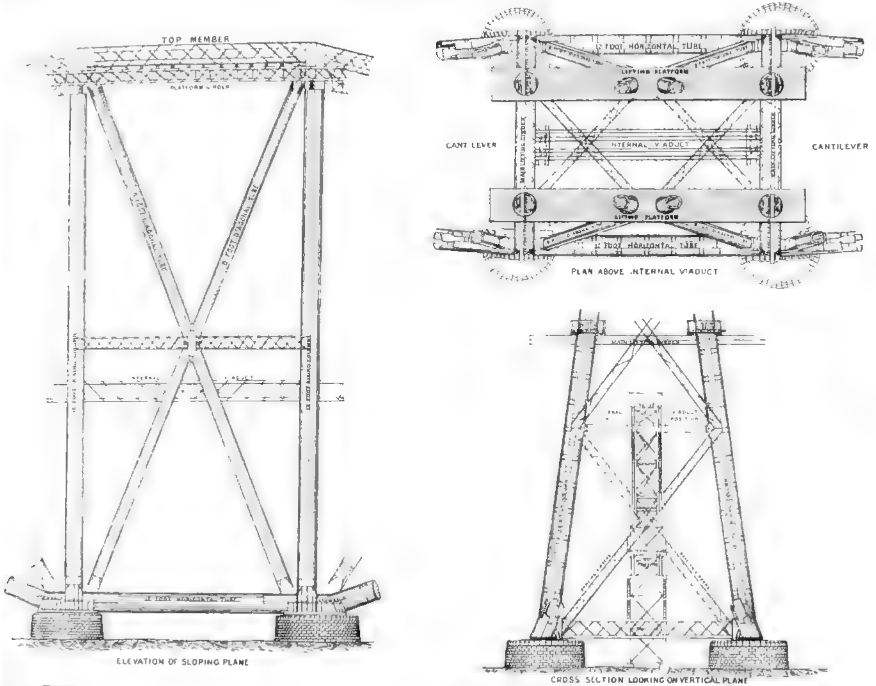
CTION LOOKING ON VERTICAL PLANE.

Spottiswoode & Co. Li

e Works.

FORTH BRIDGE FIFE MAIN STEEL PIER.



Illustrating Mr Andrew S. Biggart's Paper on The Forth Bridge Works.

The first part of the superstructure is that termed the lower bedplate. Several of these are now completed and in position. They are made up of a series of longitudinal and transverse plates, securely riveted together, and run about 37 feet long by 17′-8″ wide, with a thickness of from 3 to 4 inches. The whole plate is bolted on a number of short iron columns *in situ*, and is riveted up by a special hydraulic machine. Two girders are employed, one above and the other below the bedplate; and extending beyond it are there joined together. On each of these girders slides a hydraulic cylinder, one having a little more effective area than the other, while both are regulated by the same cock. The result is that when water is admitted the total pressure on one cylinder is greater than that on the other, thereby holding the rivet-head firmly in place while the point is being pressed up. The work thus produced is of the very highest quality; since the whole machine moves lengthwise, and the cylinders slide crosswise, the full surface of the plate is commanded by it. The riveting is also done expeditiously, the machine being capable, in ordinary work, of closing during a single shift 600 $1\frac{1}{8}''$ countersunk rivets. When finished, the bedplate is finally lowered into position.

The upper bedplate or base, on which the various connections at the foot of the rising column rest (and which collectively constitute what is termed the skewback), is proposed to be riveted in a like manner to the lower bedplate. While being riveted it will be secured to heavy steel girders instead of columns, as in the case of the lower bedplate, to keep it in true form. After lowering the upper bedplate into position, the diaphragms and various other parts will then be built on it, and riveted up by common hydraulic machines as well as by the special hydraulic machines designed by Mr. Arrol for the purpose. As many of the spaces in which riveting has to be done are very confined and difficult of access, high pressures will be used with machines correspondingly small. Thus while the ordinary pressure will still be 1,000 lbs. per square inch, it will be increased in some cases to as high as 3 tons per square inch, by a simple pressure multiplier, wrought by the ordinary 1,000 lbs. pressure. This low pressure is admitted to the large end of the compressing ram, the smaller end of which produces the increased pressure (proportional to the difference in areas) required to close up the rivet properly.

The riveting machine is very small, each cylinder weighing about half a hundredweight. The smallest proposed cylinder is only 4 inches diameter, is of the simplest form, and contains a hollow plunger provided with a single cup leather at the inner end. A spring is secured to the plunger and back end of the cylinder, for the purpose of drawing back the plunger, when the exhaust water is allowed to escape. When in place and at work the machine will be hung to the one end of a small wire, passing over a pulley, while at the other will be fixed a balance weight to relieve the operator of the weight of the machine. Two cylinders, one outside and one inside, will be required at the closing up of the rivets. Both will be connected to the compressor and wrought by it.

The horizontal tubes, skewbacks, and lower parts of all the columns will be built by ordinary cranes till they attain a height of about 30 feet above the bedplates. At this point of the 12-foot rising columns will then be commenced the longitudinal channels (through which are drilled the holes for the steel pins to pass through them and the cross girders); to these channels the cross girders will now be attached within the column, on the higher of which will be laid the two main lifting girders of the

platform. Extending between and beyond these, but at right angles, will be the other girders required to complete the rectangular platform already referred to. The principal work above this will be executed from this platform as it is being raised towards the top of the pier. In that work will be included the 12-foot rising or supporting columns, the eight-foot diagonal columns, and the bracing in the sloping planes. The vertical planes will be built similarly as the platform is raised upwards. When all is ready to be raised for the first time, the positions of the various members in the pier will be somewhat as follows. The four rising 12-foot columns will have the whole of their channels and eight of the ten plates in section, in each column, at a convenient working height above the platform. The other two plates require to be kept off at this point, to allow the main lifting girders to pass through the columns, and can only be placed in final position from underneath the main lifting girders. The columns will only be bolted together at this point, but as few more bolts will be required than those necessary to make good work when riveting up, very little labour will be lost. The eight-foot diagonal tubes in the sloping planes will also be carried up above the level of the platform. They pass between the girders, and lie in the sloping planes, and will be wholly riveted up above the level of the platform. The bracing in the vertical planes, being 12 feet wide, allows the main lifting girders to pass through it, and will be built to a large extent from a platform on the top of these girders, only the top and bottom bracing requiring to be placed and riveted in position underneath the main lifting girders, while the whole of the tubes will be built in single pieces. In the case of the bracing girders it is intended to take up and fix in position sections of a size convenient for handling with despatch under the somewhat novel circumstances around.

The riveting machines employed will be of various forms, the common type being used for such work as the bracing girders, while those for the rising and horizontal columns will be the same in principle as those riveters employed for the bedplates, with several special features to suit the different kind of work. The girders on which the cylinders slide will be similar, and similarly placed in relation to the work to be done, one being outside the column and the other inside, while at the ends they are secured to and made to slide round two circular rings by a small hydraulic cylinder. Stiffening packings or struts are placed between these circular rings and the channels of the columns inside and plates outside, to keep all in true form, and these are transferred from one point to another as the girders pass the various positions at which they are placed.

The girders are thus made to move round the complete circle, and as the hydraulic cylinders on these slide a length of 16 feet, it follows that the riveting done at each shifting of the machine is equal to this length of the completed column. To enable the riveting to be executed with the longitudinal built up channels complete, the power of the hydraulic cylinder on the inner girder is transmitted to the rivet through a lever of the third order, this cylinder having the amount of greater area necessary to exert nearly the same pressure as the cylinder on the outer girder. It is proposed that the whole machine be fixed to the platform and underneath it. It will consequently be raised with it, but during the stationary periods between the lifts, it will rivet up the 12-foot rising columns close to but always underneath the main lifting girders. Each machine is made to carry its own working platform, from which all the necessary operations will be conducted.

The raising of the main platform by the hydraulic cylinders placed within the 12-foot rising columns will be performed thus. Water will first be admitted to the lower end of two of the hydraulic cylinders in one or other of the sloping planes, sufficient to ease the main lifting girders and the two upper cross girders within the columns. The pins through these cross girders and the channels of the columns being withdrawn, water is again admitted and made to raise the one end of both main lifting girders one foot; when this is accomplished the same pins are reinserted, and the load again transferred to the cross girders. The water in the lower end of the cylinders now being allowed to escape, that in the small annular space at the other end, and which is constantly acting as a back pressure, raises the cylinders and with them the lower cross girders to the same position relative to the upper girders which they occupied before the lifting operations began. As the pin holes in the four lifting channels run the full height, the point to which the platform may be lifted at any one shift is a matter of expediency. This lift in most cases will be about 16 feet, but in any case it will be effected by single lifts of one foot at a time, as already described.

It will be apparent that the manner of lifting at the different points in each platform is exactly similar. The cylinders being in line with the 12-foot rising columns and made to raise the platform to all intents vertically, induces a slight rocking motion, which is provided for in the cylinders by planing their bottom surfaces to a very obtuse angle, the apex of which is slightly rounded off to form a better bearing.

As the platform is raised the girders in line with the sloping planes will be slid towards the centre of the bridge, each pair on either side being always kept as near as practicable at an equal distance from the centre of the rising columns.

The raising and riveting will thus be carried on till the whole arrives at the top of the pier, the platform being then in a convenient position on which to build the top members extending between the columns in line with the bridge. These will now be built, and with them the top junctions or connecting portions of the upper part of the steel pier, resembling in many respects the lower junctions termed the skewbacks. All will be riveted in position by the machines already referred to.

After the main platform has passed the point at which the internal viaduct is joined to and made to form an integral portion of the bracing in the vertical plane, the lifting of the girders, &c., of which this part is composed (and previously riveted complete) to its position will then be commenced. This will be done by means of four complete sets of columns, girders, and hydraulic cylinders. The cylinders will be placed within and fixed to the upper of two cross girders sliding on and temporarily bolted to the two vertical columns at each corner of the part to be raised. Passing between and extending across from one set of columns to the other will be the carrying girders, resting on the top of the upper cross girders and bearing the portion to be lifted into position. The ram will be made to point downwards and bear against the top of the lower cross girder. When water is admitted to the upper end of the cylinders, the bolts in the higher cross girders meanwhile having been withdrawn, the rams are forced against the lower cross girders, but as these are securely fixed to the columns, the hydraulic cylinders with the cross girders, carrying girders, and structures to be raised are bodily lifted upwards. When raised about one foot the upper cross girders are again fixed to the

columns and made to carry the load. The water is now allowed to escape, and as there is a back pressure in the cylinders similar to that in those used for raising the main platform, the rams are forced into the cylinders, and being secured to the lower cross girders are made to raise these also. This action will be repeated till all is raised to the desired height, when the girders will be quickly secured to the points previously prepared for their junction with the bracing in the vertical planes.

In addition to the several parts of the bridge already mentioned, the cantilevers will form a leading subject for careful thought. The proposed method of their erection is, however, beyond the scope of this paper, and I need only remark that all concerned see their way to successfully overcoming this part of the work also.

The approach viaducts on both sides of the Firth are presently in a forward state of progress; the girders on the south side, immediately over the water, being practically complete, having been built on timber staging, the top of which was on a level with the stone piers, so far as completed, or about 18 feet above high water. These girders will be raised to the level of the next stage erected on shore, on which will have been built during the time occupied in that lifting another pair of girders to which the first portion of the viaduct will be connected. This raising and joining to other portions still higher up will be continued till the full height is reached, when all the ten spans will be complete.

The north viaduct is in a more forward state than the south, it being wholly completed with the exception of a few of the end bays, which cannot be put in position till a higher point has been reached. The whole of the north viaduct piers are on land of a very undulating character. This necessitated some of their number being raised a considerable height so that a uniform level throughout might be attained, and all the girders built at the same time on a stage similar to that used for the other side.

The piers provide points from which the lifting can be easily and safely done. Various proposals for effecting this were discussed; that finally sanctioned by Sir John Fowler and Mr. Baker is to place underneath the end pillars of the main girders on each pier a temporary cross girder extending between and beyond these, and bearing up the whole weight, on timber blocking resting directly on the pier. In each of these temporary cross girders are placed two hydraulic cylinders, one being directly underneath each main girder; in both, the ram faces downwards. Each cylinder is provided with a separate valve to regulate its action in raising. When at rest the temporary cross girders will transmit their load to the piers, either through the blocks placed close to but between the lifting cylinders or those outside and nearer the ends of the piers, this being determined by the point at which building has to be carried on. If in the centre then the supports are outside, and *vice versâ*, the ram when lifting will bear on a prepared sole of hard wood spreading somewhat over the stonework. Great care must be exercised to keep the different bearings in the whole viaduct as near one uniform level as possible during the lifting operations, to avoid any undue straining of the main girders. As soon as the structure has been raised the full stroke of the cylinders, a new lift will be commenced, the blocks on which the rams bear having, however, been previously packed up. The height required to give ample clearance for building underneath will be about four feet.

At the ends of the north viaduct, in lieu of a bearing on the piers,

columns with all the other appliances have been provided, similar to those to be adopted for lifting the internal viaduct already described.

A hoist is provided for lifting from the ground underneath the main girders the whole of the stone, &c., required in building the piers upwards from their present level. This material will be raised while on trollies, and while still on these run along the temporary road laid on the bottom of the main girders to any or all of the piers. On arrival at any pier it can be raised and laid in position by a pair of small runners fixed to the girders immediately above each pier. The power used for raising, lowering, or traversing either way being transmitted through special horizontal winches driven by a rope extending well nigh the full length of the viaduct, the work will thus be carried on till the desired end is attained, that being reached when the rail level is fully 150 feet above high water.

Were I to state that these are the exact methods by which those parts of the bridge presently treated of will be erected, I should only be laying myself open to the ridicule of all experienced engineers, as it is a well-known fact that no undertaking of such magnitude is ever carried out to the letter of the plans originally decided upon. The foregoing are only presented as the results arrived at after full discussion by all concerned, and as the principles on which the full details will be wrought out as the work proceeds. Thus far all has gone well, no difficulty having arisen which can be said to have taxed the latent ability of either the engineers or contractors; and judging the future from the past there is every reason to conclude that in the near future the successful erection and completion of the Forth Bridge will be a matter of history.

Electric Lighting at the Forth Bridge Works.

By JAMES N. SHOOLBRED, *B.A., M.Inst.C.E.*

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

IN the summer of 1883 the contractors for this most important engineering work, Sir Thomas S. Tancred, Arrol, & Co., decided to make use of electricity in the illumination of the works required for the preparation and construction of this large undertaking. The author was by them entrusted with the preparation of the necessary plans, together with the supervision of the arrangements to enable the lighting by electricity to be thoroughly and suitably carried out.

For the construction of the bridge and the proper preparation of the large amount of steel which enters into it, very large workshops have been erected at South Queensferry, where also are concentrated the principal offices, central stores, canteen, &c. A steep incline conveys the materials from the height on which the workshops stand down to the shore of the Firth; the lines of way being then continued on a broad wooden jetty, fifty feet in width, projecting into the Firth for about seven hundred yards, up to the Queensferry main piers, whence springs the southernmost of the two large spans of the bridge.

The island of Inch Garvie, situate in mid-channel, with its group of workshops, offices, &c., necessary for the operations carried on at this isolated and exposed situation, forms the next spot requiring, at present, the use of the electric light.

On the northern, or Fife, shore of the Firth, the operations about the Fife main piers, the northern end of the second of the large spans, together with the branch workshops, stores, &c., connected therewith, as well as portions of the land viaduct extending northwards, and a part of the large stone quarries and shipping stages in the vicinity thereof, are the spots there requiring to be lighted by electricity.

The conditions to be fulfilled in the illumination of the above localities (owing to the ever-changing extent of the demands upon the lighting and the alteration in the position of each light—a matter which varied constantly, with the progress of the work in its vicinity, with the state of the tide, and from other causes) rendered it evident that the details of the arrangements for the lighting must be such as to allow of the requisite changes being effected readily and expeditiously.

Again, it was seen also that portions of the cables, wires, and other working parts of the lighting apparatus would be constantly within reach of the workmen. The primary condition, therefore, demanded a system of lighting simple in its arrangements, and which would inspire confidence in the new illuminant among the workmen.

It became evident, also, that while arc lights would be required for the outside, the offices, residential premises, stores, &c., demanded incandescent lights; and, again, that other buildings, such as the large workshops, necessitated the use of both arc and incandescent lights. Likewise, that the use of storage accumulators, as well as the transmission of power by electricity, might at some time be desirable.

To meet these various conditions it was decided: 1st, to adopt continuous current machines; 2nd, that the type of dynamo for the outside arc lights (limited to six lights in series) should not have a greater E. M. F. than 300 volts between the terminals; 3rd, that the type of dynamo for the incandescent lights, or for the arc and incandescent lights used conjointly, should be on the so-called 'compound-wound' principle, with a maximum E. M. F. of 120 volts between the terminals. The incandescent lamps, in parallel series, used with these machines to have an E. M. F. of 110 volts; while in the large workshops arc lamps in pairs (in series with one another, with the addition of a suitable resistance) would be used, where required, conjointly with the above incandescent lights.

Near to the large workshops are a number of parallel-lines of rails, forming a large uncovered workshop, and termed the 'drill-roads.' Upon these roads circulate large movable huts, each containing an engine, drilling machines, and a circular frame intended for the formation of the various steel tubes of the bridge. Here, as in the large workshops, the use of both arc and incandescent lights is necessary. But, as the exact site where each kind of light might be wanted depended upon the whereabouts of the hut upon the rails, it became necessary to provide for this, at certain fixed points, supply or 'service' boxes, whence readily fixed flexible branch-mains lead the current to the desired site of the lights.

Tenders having been invited for the carrying out of the necessary works, all the lighting on the South Queensferry side was entrusted to, and very efficiently carried out by, Messrs. Siemens Brothers & Co., Limited; while the works on the north side and on Inch Garvie were executed in a very satisfactory manner by Messrs. R. E. Crompton & Co.

The electrical plant contained in the above installations may be stated

briefly, as thirteen dynamo machines, developing about one hundred and fifty electrical horse-power; one hundred large arc lamps (of 2,000 candles each); and five hundred incandescent lamps (of 20 candles each). A total length of about twelve miles of mains has been laid down in the various circuits, exclusive of branch wires to lamps. The lighting by electricity has been carried on continuously and with satisfactory results for nearly two years, by means of the above arrangements. That the peculiar requirements of the situation, together with the storms of winter, have been successfully coped with, attest the careful and thorough manner in which both of the well-known firms who executed the works performed the part entrusted to them.

During that period of working several points of interest have arisen, and among them the following:—

1. The excessively varying conditions which are constantly occurring with regard to the outside arc lights, both as regards the number in actual use, and as to the exact position of each light (dependent greatly upon the character of the particular work going on its vicinity, the state of the tide, &c.), have been satisfactorily met in the following manner. The duty of each series-machine was limited to six arc-lights, as already stated, in order to avoid an excessive E. M. F.; the actual number lighted being varied between one and six at will, by means of resistance-frames. Furthermore, arrangements have been made on a general switch-board by which any of the circuits (sometimes as many as six in one locality) could be coupled with each other, so that the six lights or less, the complement of one machine, might be made to occur, if desired, over a circuit of very varied length (sometimes more than a mile long).

2. The lighting of the large workshops, the drill-roads, &c., demanded a combination of arc and of incandescent lights—the relative proportions between the two kinds being subject to constant variations. It was also necessary that the position should be readily changed, and also that additional lights of either kind might be easily obtainable at will. The use of 'compound-wound' dynamos, with the lamps in parallel circuit (the arc lamps being in pairs, in series with each other, with a suitable resistance in addition), provided for the first condition; while the second was complied with by the use of 'service-boxes,' containing 'plug-sockets,' into each of which was inserted the plug-end forming the extremity of a certain length of flexible twin-leading wire attached to each portable arc or incandescent lamp. The lanterns in which these several lamps were placed varied considerably in form—with arc-lights for outside or for workshop use—while for incandescents, hand-lamps, reflecting bulls-eyes, divers' or miners' lanterns, &c., might be required.

The advantages attached to this mode of working lamps in parallel circuit have proved very considerable. The ease with which lights of either kind can be added to or diminished in number, together with the comparatively low E. M. F. (110 volts), are points which must be in practice appreciated by electrical engineers. At South Queensferry alone as many as 50 arc lights (or, in lieu, 600 incandescents) are being worked on this principle. Great credit is due to Messrs. Siemens on this head, for at the time of their first being used, nothing on so extended a scale on the parallel system existed elsewhere; and certainly the working in pair-series was then quite unique.

3. Perhaps nowhere have more points of interest arisen than in the illumination of the working chambers of the deep-water caissons, which

were constructed to assist in getting in the foundations of the main piers. Each of these circular steel caissons, 60 feet in diameter and rather more in height, has its sides projecting downwards for about 8 feet below the diaphragm or ceiling which extends across the bottom of the cylinder. The lower chamber, which is thus formed, is open-mouthed and becomes a huge diving-bell. In it a number of workmen, having passed down from the surface through a tube 3′ 6″ in diameter, excavate the bottom (passing the *débris* up another tube), and thus gradually sink the caisson to the requisite depth. This operation is, of course, effected under the influence of air compressed according to the height of the water outside.

In the caissons for the Queensferry main piers, where the bottom was of clay, the illumination was effected by means of Swan incandescent lamps, twenty in number, of the ordinary 110 volt, 20 c. p. type, used throughout the works, but each protected by a strong spherical wire-guard for protection from any blow. They were pendent from the ceiling, hung on to a hook or wherever else required; each having a certain length of twin-wire attached, terminating at the other end in a contact plug. The two gutta-percha covered mains, for conveying the electric current from the dynamo, pass from the outer air into the air-lock chamber through a stuffing-box, and thence down the descent-tube into the working chamber, where they are led along the ceiling to a 'distributing-box,' and then, when required, to a second or even a third 'box.' These 'distributing-boxes' each consist of two solid copper rods, kept sufficiently apart and embedded in a wooden block, having a number of square openings in it; each opening exposing sufficient of the copper rods to allow of a good contact being made. This contact is effected by the insertion, when required, of the 'plug-end,' which is at the extremity of the flexible lead attached to each lamp; and which, at the moment of insertion, automatically lights up.

In the caissons at Inch Garvie a different mode of lighting had to be adopted, owing to the rocky bottom, which necessitated blasting; the shock of which would most probably have shattered the incandescent lamps. Here three arc-lamps (of the same type as on the surface) have been used on two circuits working in parallel (a resistance replacing the fourth lamp, which was not required). Above each lamp in the ceiling is a sort of hood, into which it is entirely withdrawn during blasting operations, in order to avoid any damage. A small pipe in the top of this hood leads off the products of combustion into the vertical shaft, and so into the air-lock, whence they are discharged into the air.

The firing of the dynamite charges is performed from the same dynamo which does the lighting. A special pair of mains are carried from the dynamo down the descent-shaft to a distributing-box on the ceiling of the working chamber. The arrangement of the plugs, &c., is the same as for the incandescent lamps, a firing fuse of a very simple construction replacing the incandescent lamp. At the top of the descent-shaft the two firing mains are both severed, and kept permanently in that state. By means of a peculiar double-contact maker, connection can be made instantaneously. When everything is ready for firing, the foreman, who alone has access to the box where is the contact-maker, fires readily the number of charges that may be required. A great deal of the successful working of the lighting arrangements in the caissons, as also in other parts on the surface, is due to the ingenuity and assiduous attention of Mr. Sydney Baynes, the resident electrician at the Forth Bridge Works.

The preceding gives a brief description of the general arrangements which have been in use, so far, for the lighting, not merely of what may be termed the (comparatively) permanent part of the works (such as the offices, stores, workshops, &c.), but also for the actual operations on the foundations of the bridge itself. Shortly this last-named stage will be at an end, and the erection of the superstructure will necessitate, probably, far different arrangements—lights scattered widely and of a very portable character. Then may perhaps come into play, as valuable adjuncts, those two other applications of the electric current—its utilisation in connection with storage accumulators, and for the transmission of power—objects the possibility of the future use of which led the author to adopt continuous current dynamo machines for the lighting by electricity of the Forth Bridge Works.

The New Tay Viaduct. *By* CRAWFORD BARLOW, *B.A.*, *M.Inst.C.E.*

[PLATE VII.]

[A communication ordered by the General Committee to be printed *in extenso* among the Reports.]

CONSIDERABLE interest is attached to this undertaking, because of the comparatively few viaducts of so great length crossing tidal water in such an exposed position, and also because of the fact that it is to replace the Tay Bridge, which was rendered useless by the memorable disaster of December 1879. The Tay Viaduct is being constructed at the side of, and 60 ft. distant from, the bridge, the standing portions of which are used for the conveyance of men and materials, and in otherwise assisting the construction of the new work. The total length is 3,600 yards, *i.e.*, a little over two miles. The number of spans is eighty-five, of dimensions varying from 50 ft. to 230 ft., and the height of the rails above high water where greatest—at the southern end—is 83 ft. At the four navigable spans near the middle of the river the height is 79 ft., which gives a clear headway for shipping of 77 ft.; and from this point to the Dundee or north end there is a falling gradient of 1 in 114, which reduces the rail level at the Dundee end to about 25 ft. above high water.

For the purposes of description the work may be divided into three parts—(1) the arching at Wormit, at the southern end of the viaduct; (2) the Esplanade spans, at the Dundee or northern end; and (3) the viaduct proper, *i.e.*, that part which extends over the tidal water.

1. The arching at Wormit consists of four arches of 50ft. span, with their abutments and piers—Nos. 1 to 4—the whole being built of brick. In plan the width of the arching is equal to that of the viaduct at the northern end, but widens out at the southern end to accommodate the junction of the Newport branch with the Edinburgh main line.

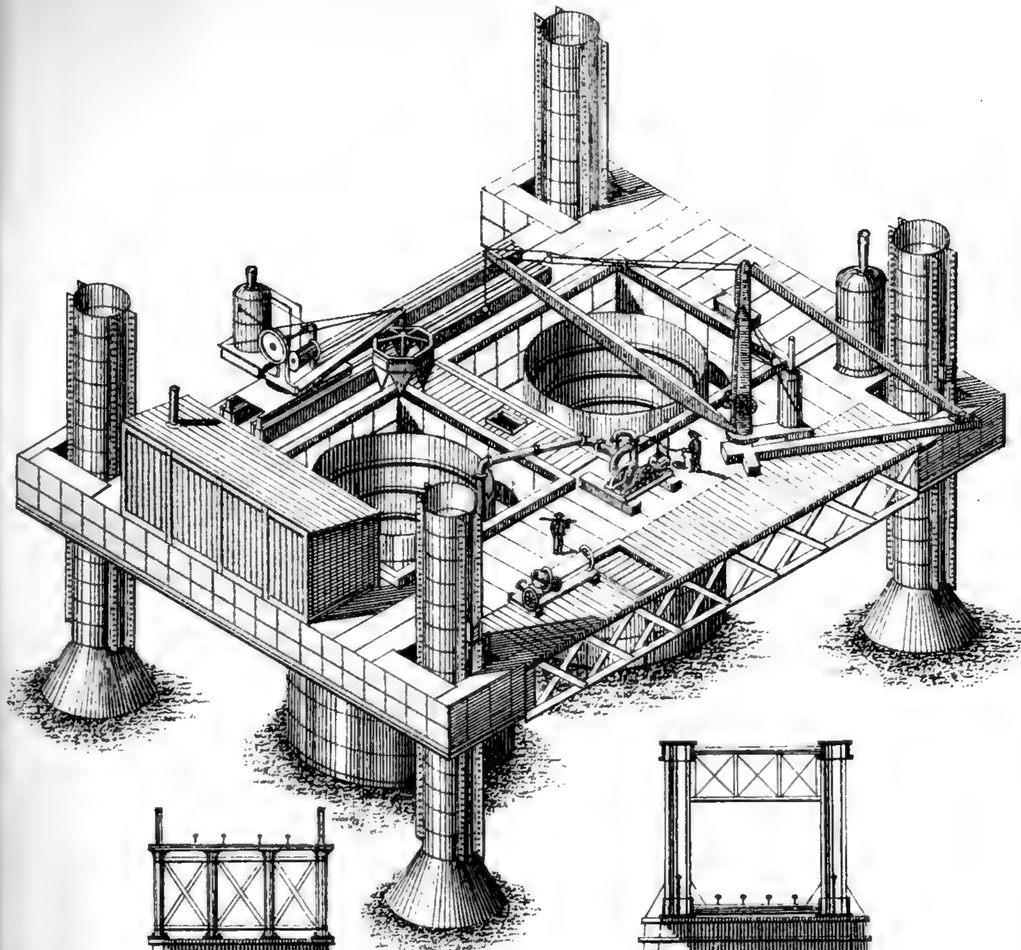
2. The Esplanade spans at the Dundee or north end of the viaduct are seven in number, between piers Nos. 78 and 85, and derive their name from the fact that they cross the existing and proposed extension of the Dundee Esplanade. Two of these spans—between piers 78 and 80—consist of brickwork piers and wrought-iron skew arches, built to suit the direction of the proposed Esplanade; next to these are four spans of wrought-iron girders supported on cast-iron columns, standing on granite and brick-

work bases. The last span is over the existing Esplanade, and consists of a pair of hog-backed girders of 100 ft. span resting on two brick piers.

3. The viaduct proper has seventy-four spans of various dimensions, consisting of wrought-iron girders resting on piers—Nos. 4 to 78. The piers are constructed with a pair of cylinders connected at a short distance above high water, and on which is a wrought-iron structure of heights varying from 10 ft. to about 70 ft., the top of which carries the girders. The cylinders of about two-thirds of the piers—Nos. 5 to 53—are constructed with a wrought-iron caisson lined with brickwork and filled with concrete up to low-water level; above this is a brick shaft also filled with concrete. Those for the remaining third—Nos. 54 to 77—are of cast iron lined for their whole height with brickwork, and filled with concrete. The bases of the cylinders are of various diameters—10 ft. for the piers of the smallest spans to 23 ft. for those of the largest; and, except in the few cases where rock is met with, the cylinders are being sunk to depths varying from 20 ft. to 30 ft. below the bed of the river, so as to be out of reach of the scouring action of the tide. Before building the upper part, the cylinder foundations are tested with a weight 33 per cent. greater than the maximum load which can come upon them. At $1\frac{1}{2}$ ft. above high water there is a strong connecting piece between the pair of cylinders constructed with cast-iron girders, wrought-iron ties, brickwork and concrete; its height is 8 ft., and width nearly equal to that of the cylinders. On the top of each cylinder and above the connecting piece rises an octagonal shaft of wrought-iron, the base of which is formed of a gridiron framework of channel irons attached to the cylinders by long wrought-iron bolts. These shafts are joined together near the top of the pier by a semicircular arch, forming at the top one structure sufficiently wide to carry the girders. The whole of this structure is constructed of wrought-iron plates, riveted together with channel, Tee, and angle irons. The dimensions of the girders for the seventy-four spans are very various, and are as follows:—Eleven spans with 245 ft. girders, two spans with 227 ft. girders, one span with 162 ft. girders, thirteen spans with 145 ft. girders, twenty-one spans with 129 ft. girders, one span with 113 ft. girders, twenty-four spans with 71 ft. girders, and one span with 56 ft. girders. The thirteen large spans, with 245 ft. and 227 ft. girders—between piers 28 and 41—are near the middle, and over the navigable channel of the river. At each of these spans there is a pair of hog-backed girders, the rails being laid between and at the bottom of them. The rest of the spans—twenty-four on the south side, and thirty-seven on the north side—are constructed with four rectangular girders, the two outer ones being the girders of the old bridge. At these spans the rails are laid on top of the girders. The flooring or deck plating is corrugated in form, and is constructed, at the large spans, of channel irons and plates riveted together, so as to form alternate troughs and ridges; and at the smaller spans of steel plates hydraulically pressed into a corrugated shape.

On each side of the viaduct for its whole length is a wrought-iron latticework parapet or wind screen 5 ft. high above the rails.

The Act of Parliament for the undertaking was obtained in 1881, but the contract for the works was not settled until April 1882, owing to a question raised with the Board of Trade concerning the ruins and *débris* of the old bridge. The present state of the works is as follows:—The arching at Wormit and the Esplanade spans are completed to the level of



PONTOON.

the railway, and the greater part of the parapets of the Esplanade spans is erected. At the viaduct proper the cylinders for fifty-eight out of the total of seventy-three piers have been sunk. The method adopted by Messrs. Arrol, the contractors for the works, for sinking them is specially ingenious. It consists of a rectangular pontoon, having at each of its corners vertical wrought-iron tubular legs, which can be raised or lowered hydraulically. When these are lowered to the bed of the river the pontoon can be raised out of the water, and thus form a stage for the machinery, materials, and men required in sinking and filling the cylinders. In the pontoons are two openings, within which the cylinders are pitched and adjusted in position. The excavation is effected by means of steam diggers, and as the digging proceeds the cylinders follow down, until the required depth is reached. When the sinking and filling is completed, the supporting tubes or legs are raised from the bottom, and the pontoon floated into position for another pier. It may be mentioned that, in raising or lowering these legs, great use is made of the tide. Four of these pontoons have been used for sinking the cylinders. The wrought-iron structures or shafts of four piers on the south side, and of twenty-four piers on the north side, have been erected. The girders for one span on the south side and nine spans on the north side are erected in position on the piers, and nearly all the girders, except those for the large spans, are built and ready for erection. The girders and flooring for each of the thirteen large spans are being built entire on a staging erected for this purpose at the south end of the viaduct, and arrangements are being made by which the girders and flooring for each span complete will be floated out to position in the viaduct, and placed on the cylinders; they will then be raised hydraulically to their proper height, the wrought-iron shafts of the piers being built up at the same time. The general progress of the whole viaduct may be briefly stated to be as follows:—Nearly seven-eighths of the foundations of the eighty-six piers are put in; almost one-half of the piers are built up to the level of the girders, &c., and out of the total length of 3,600 yards, 540 yards—*i.e.* rather more than one-eighth—is complete and ready for the railway. All the wrought-iron and steel for the work is carefully tested, the tests being that the wrought-iron must be capable of bearing a tensile strain of 22 tons per square inch, with an extension of 6·25 per cent. in a length of 8 in.; and the steel 27 tons per square inch, with an extension of 15 per cent. The whole of the iron and steel work is shaped and drilled at Messrs. William Arrol & Co.'s works at Glasgow, preparatory for erection either on the shores or in position in the viaduct. In executing these works a great amount of plant is required, and a number of ingenious machines and clever contrivances have been devised and brought into operation by the contractors for the better performance of the work and saving of labour.

TRANSACTIONS OF THE SECTIONS.

TRANSACTIONS OF THE SECTIONS.

Section A.—MATHEMATICAL AND PHYSICAL SCIENCE.

President of the Section—Professor G. Chrystal, M.A., F.R.S.E.

THURSDAY, SEPTEMBER 10.

The President delivered the following Address:—

When a man finds himself unexpectedly in some unusual situation his first impulse is to look round and see how others have done in like circumstances. I have accordingly run through the addresses of my predecessors in the honourable office of president of Section A, which is fated this year to be filled somewhat unworthily. This examination has, I am bound to say, comforted me not a little. I have found precedents for all kinds of addresses, long and short, even apparently for none at all. The variety of subjects is also suggestive of great latitude. I have found reviews of the progress of mathematical and physical science, discussions of special scientific subjects, dissertations on the promotion of scientific research, and on the teaching and diffusion of science, all chosen in their turn for the subjects of this opening address.

Following some of the most eminent of my forerunners, I propose to be brief; following the last of them, Professor Henrici, I shall take for my subject, so far as I have one, the Diffusion of Scientific Knowledge. Apart from the fact that Professor Henrici's address greatly interested me, and that I find many of his conclusions in agreement with the results of my own experience, and that, therefore, I wish to second him with all my power, I have other reasons for this choice. For more than half the year I am employed with absolute continuity in teaching mathematics, and it has happened for the last eight years or so that the other half has been mainly occupied in a variety of ways with science-teaching generally. This is the thing concerning which I have had most experience, and I hold it to be the most respectful course towards my audience to speak to them on the subject that I know best.

Ever since I began to study science I have been deeply interested in the question of how it could best be taught. I believe my meditations in that direction were awakened by some unsuccessful boyish efforts to apply to the satisfaction of a ploughman, who was my friend and confidant, certain principles of natural philosophy to explain the action of his plough. Wisely and unwisely I have always been ardent about the improvement of scientific teaching. I was so long before I dreamt that I should one day be called upon to put my ideas through the cold ordeal of practice. It would not be becoming that I should speak at any time, more particularly to-day, regarding the success of my own efforts, or even regarding my alternate fits of hopefulness and despair. It is enough to say that, in such a cause,

> ''Tis better to have loved and lost,
> Than never to have loved at all.'

The British Association, by its title, exists for the advancement of science. Now, I hold that one of the essential conditions for that advancement is the existence of a scientific public—a public, like the Athenians of old, eager to hear and tell of some new truth; eager to discuss and eager to criticise; ready to appreciate what is novel; to receive it if sound, to reject it if unsound. It is to such a public that the British Association appeals, and certainly in the past it has not found its public wanting in generosity. What I should wish to see is less of mere friendly onlooking and more participation in the dance.

I am not speaking now merely of a professional public, such as is so prominent in Germany for instance, made up of teachers and others professionally concerned with science. I refer mainly to that amateur but truly expert public which has always been so honourable a feature of English science, as examples of which I may mention Boyle and Cavendish in former days, and Joule and Spottiswoode in our own. It is quite true that much of that scientific public came in days of yore from the leisured class, whose ratio to the rest of the nation will not improbably decrease in the course of our social development. I think, however, that the loss we may thus sustain will be more than compensated by the continual increase of those who have received higher education of some kind or other, and whose daily occupations give them an interest, direct or indirect, in one or more branches of science.

It may not be amiss to insist for a little on the advantages to science of a great body of men unofficially engaged in scientific research, in writing regarding science, or even in merely turning scientific matter over in their minds. It will not have escaped the notice of those among you who have studied the history of science, that few scientific ideas spring up suddenly without previous trace or history. It is perfectly true that in many cases some mind of unwonted breadth and firmness is required to formulate the new doctrine, and carry it to manifold fruition; but a close examination always shows that the sprite was in the air before the Prospero came to catch him. It is very striking to notice, in the history of Algebra for instance, long periods in which great improvements were effected in the science, which cannot be traced to any individual, but seem to have been due merely to the working of the minds of scientific men generally upon the matter, one giving it this little turn, another that, in the main always for the better. Like every other thing that has the virtue of truth in it, science grows as it goes, not like the idle gossiping tale by the casual accretion of heterogeneous matter, but by the chemical combination of pure element with pure element in reasonable proportion.

I know of no greater advantage for science than the existence of an army of independent workers sufficiently enlightened for self-criticism, who shall test the results and theories of their day. Great and indispensable as are the uses of professional schools of scientific workmen, they are open to one great and insidious danger. The temptation there to swear by the word of the master is often irresistible. Not to speak of its being often the readiest avenue to fame and profit, it is the perfectly natural consequence of the contact of smaller mind with greater.

There are few things where the want of an enlightened scientific public strikes an expert more than the matter of scientific text-books. If the British public were educated as it ought to be, publishers would not be able to palm off upon them in this guise the ill-paid work of fifth-rate workmen so often as they do; nor would the scientific articles and reviews in popular journals and magazines so often be written by men so palpably ignorant of their subject.

We all have a great respect for the integrity of our British legislators, whatever doubts may haunt us occasionally as to their capacity in practical affairs. The ignorance of many of them regarding some of the most elementary facts that bear on everyday life is very surprising. Scientifically speaking, uneducated themselves, they seem to think that they will catch the echo of a fact or the solution of an arithmetical problem by putting their ears to the sounding-shell of uneducated public opinion. When I observe the process which many such people employ for arriving at what they consider truth, I often think of a story I once heard of an eccentric German student of chemistry. This gentleman was idle, but, like all his nation, systematic. When he had a precipitate to weigh, instead

of resorting to his balance, he would go the round of the laboratory, hold up the test-tube before each of his fellow-students in turn, and ask him to guess the weight. He then set down all the replies, took the average, and entered the result in his analysis.

I will not take up your time by insisting upon the necessity of the diffusion of science among that large portion of the public who are, or ought to be, appliers of scientific knowledge to practical life. That part of my theme is so obvious, and has been of late so much dwelt upon, that I may pass it by and draw your attention to another place in which the shoe pinches. All of you who have taken any practical interest in the organisation of our educational institutions must be aware of the great difficulty in securing the services of non-professional men of sufficient scientific knowledge to act on School Boards, and undertake the direction of our higher schools. It is no secret among those who carefully watch the course of the times in these matters that our present organisation is utterly insufficient; that it has not solved, and shows every day less likelihood of solving, the problems of higher education. This arises, to a great extent, from the fact that a scientifically educated public of the extent presupposed by the organisation really does not at present exist.

If the existence of a great scientific public be as important as I think I have shown it to be, it must be worth while to devote a few moments to the consideration of the means we adopt to produce it both in the rising and in the risen generation.

It would naturally be expected that we should look carefully to the scientific education of our youth, to see that the best men and the best means that could be had were devoted to it; that we should endeavour to make for them a broad straight road to the newest and best of our scientific ideas; that we should exercise them when young on the best work of the greatest masters; familiarise them early with the great men and the great feats of science, both of the past and of the present; that we should avoid retarding their progress by making the details and illustrations or particular rules and methods ends in themselves. Granting that it is impossible to bring every learner within reach of the fullest scientific knowledge of his time, it would surely be reasonable to take care that the little way we lead him should not be along some devious by-path, but towards some eminence from which he might at least *see* the promised land. The end of all scientific training of the great public I take to be, to enable each member of it to look reason and nature in the face, and judge for himself what, considering the circumstances of his day, may be known, and not be deceived regarding what must to him remain unknown. If this be so, surely the ideal of scientific education which I have sketched is the right one: yet it is most certainly not the ideal of our present system of instruction. To attain conviction on that head it is sufficient to examine the text-books and examination papers of the day.

Let us confine ourselves for the present to the most elementary of all the exact sciences, viz., geometry and algebra. These two, although among the oldest, are, as Professor Cayley very justly reminded the Association not long ago, perhaps the most progressive and promising of all the sciences. Great names of antiquity are associated with them, and in modern times an army of men of genius have aided their advance. Moreover, it cannot be said that this advance concerns the higher parts of these sciences alone. On the contrary, the discoveries of Gauss, Lobatschewsky, and Riemann, and of Poncelet, Möbius, Steiner, Chasles, and Von Staudt, in geometry, and the labours of De Morgan, Hamilton, and Grassmann, not to mention many others, in algebra, have thrown a flood of light on the elements of both these subjects. What traces of all this do we find in our school books? To be sure *antiquity* is stamped upon our geometry, for we use the text-book of Euclid, which is some two thousand years old; but where can we point to the influence of *modern* progress in our geometrical teaching? For our teaching of algebra, I am afraid, we can claim neither the sanction of antiquity nor the light of modern times. Whether we look at the elementary, or at what is called the higher teaching of this subject, the result is unsatisfactory. With respect to the former, my experience justifies the criticism of Professor Henrici; and I have

no doubt that the remedy he suggests would be effectual. In the higher teaching, which interests me most, I have to complain of the utter neglect of the all-important notion of algebraic form. I found, when I first tried to teach University students co-ordinate geometry, that I had to go back and teach them algebra over again. The fundamental idea of an integral function of a certain degree, having a certain form and so many coefficients, was to them as much an unknown quantity as the proverbial x. I found that their notion of higher algebra was the solution of harder and harder equations. The curious thing is that many examination candidates, who show great facility in reducing exceptional equations to quadratics, appear not to have the remotest idea beforehand of the number of solutions to be expected; and that they will very often produce for you by some fallacious mechanical process a solution which is none at all. In short, the logic of the subject, which, both educationally and scientifically speaking, is the most important part of it, is wholly neglected. The whole training consists in example grinding. What should have been merely the help to attain the end has become the end itself. The result is that algebra, as we teach it, is neither an art nor a science, but an ill-digested farrago of rules, whose object is the solution of examination problems.

The history of this matter of problems, as they are called, illustrates in a singularly instructive way the weak point of our English system of education. They originated, I fancy, in the Cambridge Mathematical Tripos Examination, as a reaction against the abuses of cramming bookwork, and they have spread into almost every branch of science teaching—witness test-tubing in chemistry. At first they may have been a good thing; at all events the tradition at Cambridge was strong in my day, that he that could work the most problems in three or two and a half hours was the ablest man, and, be he ever so ignorant of his subject in its width and breadth, could afford to despise those less gifted with this particular kind of superficial sharpness. But, in the end, it came all to the same: we were prepared for problem-working in exactly the same way as for bookwork. We were directed to work through old problem papers, and study the style and peculiarities of the day and of the examiner. The day and the examiner had, in truth, much to do with it, and fashion reigned in problems as in everything else. The only difference I could ever see between problems and bookwork was the greater predominance of the inspiriting element of luck in the former. This advantage was more than compensated for by the peculiarly disjointed and, from a truly scientific point of view, worthless nature of the training which was employed to cultivate this species of mental athletics. The result, so far as problems worked in examinations go, is, after all, very miserable, as the reiterated complaints of examiners show; the effect on the examinee is a well-known enervation of mind, an almost incurable superficiality, which might be called Problematic Paralysis—a disease which unfits a man to follow an argument extending beyond the length of a printed octavo page. Another lamentable feature of the matter is that an enormous amount of valuable time is yearly wasted in this country in the production of these scientific trifles. Against the occasional working and propounding of problems as an aid to the comprehension of a subject, and to the starting of a new idea, no one objects, and it has always been noted as a praiseworthy feature of English methods, but the abuse to which it has run is most pernicious.

All men practically engaged in teaching who have learned enough, in spite of the defects of their own early training, to enable them to take a broad view of the matter, are agreed as to the canker which turns everything that is good in our educational practice to evil. It is the absurd prominence of written competitive examinations that works all this mischief. The end of all education nowadays is to fit the pupil to be examined; the end of every examination not to be an educational instrument, but to be an *examination* which a creditable number of men, however badly taught, shall pass. We reap, but we omit to sow. Consequently our examinations, to be what is called fair—that is, beyond criticism in the newspapers—must contain nothing that is not to be found in the most miserable text-book that any one can cite bearing on the subject. One of my students, for

example, who was plucked in his M.A. examination, and justly so if ever man was, by the unanimous verdict of three examiners, wrote me an indignant letter because he believed, or was assured, that the paper set by the examiners could not have been answered out of Todhunter's Elementary Algebra. I have nothing to say, of course, against that or any other text-book, but who put it into the poor young man's head that the burden lay with me to prove that the examination in question ought to contain nothing but what is to be found in Todhunter's Elementary Algebra? The course of this kind of reasoning is plain enough, and is often developed in the newspapers with that charming simplicity which is peculiar to honest people who are, at the same time, very ignorant and very unthinking. First, it follows that lectures should contain nothing but what is to be found in every text-book; secondly, lectures are therefore useless, since it is all in the text-book; thirdly, the examination should allude to nothing that is not in the text-books, because that would be unfair; fourthly, which is the coach or crammer's deduction, there should be nothing in the text-book that is not likely to be set in the examination. The problem for the writer of a text-book has come now, in fact, to be this—to write a booklet so neatly trimmed and compacted that no coach, on looking through it, can mark a single passage which the candidate for a minimum pass can safely omit. Some of these text-books I have seen, where the scientific matter has been, like the lady's waist in the nursery song, compressed 'so gent and sma',' that the thickness of it barely, if at all, surpasses what is devoted to the publisher's advertisements. We shall return, I verily believe, to the Compendium of Martianus Capella. The result of all this is that science, in the hands of specialists, soars higher and higher into the light of day, while educators and the educated are left more and more to wander in primeval darkness.

When our system sets such mean ends before the teacher, and encourages such unworthy conceptions of education, is it to be wondered at that the cry arises that pupils degenerate beneath even the contemptible standards of our examinations? These can hardly be made low enough to suit the popular taste. It is no merit of the system we pursue, but due simply to the better among our teachers, men many of them who work for little reward and less praise, that we have not come to a worse pass already. Some even of the much-abused crammers have conceptions of a teacher's duty far higher than the system-mongers of the day, whom it is their special business to outwit; and it is but fair to allow to such of these also as deserve it part of the credit of stemming the torrent of degeneration. We place our masters in positions such that their very bread depends upon their doing what many of them know and will acknowledge to be *wrong*. Their excuse is, 'We do so and so because of the examination.'

The cure for all this evil is simply to give effect to a higher ideal of education in general, and of scientific education in particular. Science cannot live among the people, and scientific education cannot be more than a wordy rehearsal of dead text-books, unless we have living contact with the working minds of living men. It takes the hand of God to make a great mind, but contact with a great mind will make a little mind greater. The most valuable instruction in any art or science is to sit at the feet of a master, and the next best to have contact with another who has himself been so instructed. No agency that I have ever seen at work can compare for efficiency with an intelligent teacher, who has thoroughly made his subject his own. It is by providing such, and not by sowing the dragon's teeth of examinations, that we can hope to raise up an intelligent generation of scientifically educated men, who shall help our race to keep its place in the struggle of nations. In the future we must look more to men and to ideas, and trust less to mere systems. Systems have had their trial. In particular, systems of examination have been tested and found wanting in nearly every civilised country on the face of the earth. Backward as we are here, we are stirring. The University of London, after rendering a great service to the country by forcing the older universities to give up the absurd practice of restricting their advantages to persons professing a particular shade of religious belief, has for many years pursued its career as a mere examining body. It has done so with rare advantages in the way of Government aid, efficient organisation, and an unsurpassed staff

of examiners. Yet it has been a failure as an instrument for promoting the higher education—foredoomed to be so, because, as I have said, you must sow before you can reap. At the present time, with great wisdom, the managers of that institution have set about the task of really fitting it out for the great end that it professes to pursue. If they succeed in so doing, they will confer upon the higher education one of the greatest benefits it has yet received. They have an opportunity before them of dethroning the iron tyrant Examination which is truly enviable. This movement is only one of the signs of the times. Among the younger generation I find few or none that have any belief in the 'learn when you can and we will examine you' theory; and small wonder, for they have tasted the bitterness of its fruit. *Laissez faire* as a method in the higher education no longer holds its place, except in the minds of inexperienced elderly people, who cling, not unnaturally, to the views and fashions which were young when they were so.

All the same, the task of reformation is not an easy one. Examinations have a strong hold upon us, for various reasons, some good, some bad, but all powerful. In the first place, they came in as an outlet from the system of patronage, which, with many obvious advantages, some of which are now sorely missed, had become unsuited to our social conditions. There is a certain advantage in examinations from the organiser's point of view, which any one who, like myself, has to deal with large quantities of pretty raw material will readily understand. Again, there is an orderly bustle about the system that pleases the business-loving eye of the Briton. Yearly the printed sheets go forth in every corner of the land. The candidates meet and, in the solemn silence of the examination hall, the inspector, the local magnate, or the professor, sits, while for two or three busy hours the pens go scratching over the paper. A feeling of thankfulness comes over the important actor in this well-ordered scene, that the younger generation have such advantages that their fathers never knew. It is only when the answers are dissected in the examiner's study that the rottenness is revealed underlying the fair outward skin. But then the examiner must go by his standards; he must consider what is done elsewhere, and what is to be reasonably expected. Accordingly he takes his report and quickly writes so many per cent. passed. Then the chorus of reporting examiners lift up their voices in wonderful concordance; and all, perhaps even the examiners, are comforted. There is something attractive about the whole thing that I can only compare to the pleasure with which one listens to the hum of a busy factory or to the roaring of the forge and ringing of the anvil. But what avails the hum of the factory if the product be shoddy, and what the roar of the forge and the ring of the anvil if the metal we work be base?

In conclusion, let us consider for a moment what might be done for the risen generation, who are too old to go formally to school, and yet not too old to learn. In their education such bodies as the British Association might be very helpful. Indeed, in the past, the British Association has been very helpful in many ways. It can point to an admirable series of reports on the progress of science, for which every one who, like myself, has used them, is very grateful. It is much to be desired that these reports should be continued, and extended to many branches of science which they have not yet covered.

The Association has at present, I believe, a committee of inquiry into science-teaching generally. This is typical of a kind of activity which the Association might very profitably extend. This Association, with its long list of members bristling with the names of experts in every science, not drawn from any clique or particular centre, but indiscriminately from the whole land, might take upon itself to look into the question of scientific text-books and treatises. Even if it did not set up a censorship of the scientific press, which might be an experiment of doubtful wisdom, although some kind of interference seems really wanted now and then, it might set itself to the highly useful work of filling the gaps in our scientific literature. There is nothing from which the English student suffers so much as the want of good scientific manuals. The fact is that the expense of getting up such books in this country is so great, and the demand for them, though steady, yet so limited, that it will not pay publishers to issue them, let alone

remunerate authors to write them. In my student-days the scarcity was even greater than it is now, and in fact then no one could hope to get even a reasonable acquaintance with the higher branches of exact science unless he had some familiarity with French or German at the very least—a familiarity which was rare among my fellow-students either in England or in Scotland. Might not the British Association now and then request some one fitted for the task to write a treatise on such and such a subject, and offer him reasonable remuneration for the time, labour, and skill required?

Another field in which the Association might profitably extend its labours appears to me to be the furnishing of reports, from time to time, on the teaching of science in other countries, and the drawing up of programmes of instruction for the guidance of schoolmasters and of those who are reading for their own instruction. There is no need to impose these programmes on any one. I would leave as much freedom to the teacher as I would to the private student. The programme drawn up by the Society for the Improvement of Geometrical Teaching, for example, has been very useful to me as a teacher, although I do not follow it or any other system exclusively. The great thing is not to fall asleep over any programme or system. For the matter of that, Euclid would do very well in the earlier stages of school instruction at least, provided he were modernised, and judiciously discarded at that part of the student's career where a lighter vehicle and more rapid progress becomes necessary. In such programmes as I contemplate the bearing of recent discovery on the elements of the various sciences could be pointed out, and the general public kept in this way from that gross ignorance into which they are at present allowed to fall.

The British Association has of late, I believe, given its attention to the encouragement of local scientific activity. There can be no doubt that much could be done in this way that is not done at present. The concentration of scientific activity in metropolitan centres is beginning to have a depressing effect in Great Britain. This is seen in the singularly unequal way in which Government aid is distributed over the country. Large sums are spent—sometimes we outsiders think not to the best purpose—through certain channels, simply because these channels happen to have a convenient opening in some Government office in London, or in some place in that important city which has easy access to the ruling powers; while applications on behalf of other objects not less worthy are met with a refusal which is sometimes barely courteous. The result is that local effort languishes, and men of energy, finding that nothing can be done apart from certain centres, naturally gravitate thither, leaving provincial desolation to become more desolate.

I think our great scientific societies—the Royal Societies of London and Edinburgh and the Royal Irish Academy—might do more than they do at present to prevent this languishing of local science, which is so prejudicial to the growth of a scientific public. Besides their all-important publishing function, these bodies have for a considerable time back been constituted into a species of examining and degree-conferring bodies for grown-up men. That is to say, their membership has been conferred upon a principle of *exclusion*. Instead of any one being *admitted* who is willing to do his best, by paying his subscription or otherwise, to advance science, every one is *excluded* who does not come up to the standard of a certain examining body. So far is this carried in the case of the Royal Society of London, that there is an actual competitive examination, on the result of which a certain number of successful candidates are annually chosen. Now, against this proceeding by itself I have nothing to say, except that it appears to belong to the pupillary age both of men and nations. It is not the honouring of the select few that I think evil, but the exclusion of the unhonoured many. The original intention in founding these societies was to promote the advancement of science. How that is done by excluding any one, be it the least gifted among us, who is honestly willing to contribute his mite towards the great end, fairly passes my comprehension. If it is thought necessary, for the proper cultivation of the scientific spirit among us, that the degree-conferring function should be continued, let there by all means be an inner court of the temple, a place for titular immortals; but let there

be also a court of the Gentiles, where those whose fate or whose choice it is to serve science unadorned may find a modest reception. I believe that the adoption of this suggestion would enormously extend the usefulness of our great scientific societies, and give to their voice a weight which it never had before. At all events, if the trammels of tradition, or some better reason with which I am unacquainted, should prevent them from broadening their basis in the way I indicate, nothing prevents the British Association, with its more liberal constitution, from considering what may be done for the scientific plebeian.

There is one other function of the British Association in connection with which I wish to venture another suggestion. During the annual meeting, scientific men have an opportunity of making each other's acquaintance. Great men exchange ideas with great men; and, most important of all, young and little men have a chance, rarely otherwise afforded, of taking a nearer view of the great. What I would suggest for consideration is, whether it might not be possible to form an organisation which would in a certain sense carry this advantage through the whole year. I have already alluded more than once to the difficulties that the scientific public—and here I include professional men generally, in fact all but the leaders of science—have in keeping pace with recent advances. Would it not be possible to have an arrangement enabling at least every large centre of the higher education to have periodically the benefit of communion with and instruction from the high priests of the various branches of science? How glad we, the teachers of science in Edinburgh for example, would be to have a course of lectures once every three or four years from Professors Cayley, Sylvester, Stokes, Adams, or Lord Rayleigh. In this way effect would be given to the principle which cannot be too much insisted upon, that the power of the spoken word far exceeds that of the written letter. Not only should we learn from the mouths of the prophets themselves the highest truths of science, but the present generation would thus come to know face to face, as living men, those whose work will be the glory of their time and a light for future ages. From the want of a proper circulating medium, the influence of great scientific men very often does not develop until they and the secrets of their insight have gone from among us. The object of what I propose is to make these men more of a living power in their own lifetime.

The following Papers were read:—

1. *On the Dilatancy of Media composed of Rigid Particles in Contact.*[1] *By* Professor OSBORNE REYNOLDS, *M.A., F.R.S.*

In the account which Professor Reynolds gave of his paper, he did not submit a complete dynamical theory, but discussed a very fundamental property of granular masses. To this property he gives the name of *dilatancy*. It is exhibited in any arrangement of particles where change of bulk is dependent upon change of shape. In the case of fluid matter, as we know it, change of shape and volume are independent. In solids they are sometimes not separable. With granular masses the result is different—change of shape *always* produces change of volume. And further, in every case, if change of volume is prevented all change of form is impossible.

If we suppose the granular masses to be spherical, no granule can change its position without disturbing the adjacent particles—for the granules are all supposed to be perfectly rigid, and to be absolutely in contact; and the internal particles are fixed if the external ones are. In illustration Professor Reynolds showed a model of connected spherical bodies arranged in crystalline form. This model showed the arrangement of the particles corresponding to, say, the condition of least possible density of the whole mass (about one-half the density of the separate spheres). The shape could then be altered to that which corresponds to maximum density—the change taking place by sliding of the particles one upon another. Between the extreme states there are intermediate stages of equilibrium corresponding to maximum-minimum positions, where alteration in one direction produces decrease of density, and in the other increase of density.

[1] Published in full in *Phil Mag.* Dec. 1885, p. 469.

In a complete treatment of the problem, friction must be closely considered; but in the experiment shown it is not of consequence, the result being independent. The above statements will be true of any continuous mass of granules if we hold the boundaries.

This principle of the dilatancy of such granular media explains many phenomena of common occurrence. For example, take a sack of corn, if set on end, it remains perfectly flexible; but if placed on its side it becomes hard, and its shape will not alter. Now take an indiarubber sack, fill it with shot—it remains perfectly flexible in all positions. The reason for this difference of behaviour is that in the former case the boundary of the granular mass is inextensible, while in the latter it allows increase of internal volume. So if it be possible with an extensible envelope to impose a limit to the volume of the contents, effects similar to those obtained with the inextensible boundary may be expected: and this can be done. If we place some shot (No. 6 was used in the experiment) in a thin indiarubber bag, and add a certain amount of water, we obtain the result wished. For if the amount of water added be such that the spaces between the granules when in close arrangement are all filled by it, while with a wide arrangement the amount is not enough, a point will be reached in passing from the first to the second arrangement such that any further change of volume, and consequently of shape, would produce a vacuum. When this stage is reached the whole mass becomes perfectly hard. Professor Reynolds illustrated this by means of a ball of shot to which a glass tube open at the end was fitted. With a close arrangement of the shot, the water, which was coloured, stood high in the tube; but when pressure was applied to the bag, the level was lowered. This was shown also with a ball containing sand instead of shot. The water level sank till the whole was at maximum density, and, still more pressure being applied, the level again rose, the maximum having been passed. In these experiments about 6 per cent. of the water was free at the top of the ball with the close arrangement of granules. When another ball containing 20 per cent. of free water was used, the hard condition could only be approximated to by pressure, and then passed. So long as the maximum is not passed in this case the ball springs back to its original state when the pressure is released. But if the maximum be passed, it will not spring back. If some of the water be now let out, the maximum cannot be passed, except by shaking, and, if the flattened ball be then turned on edge, it will bear a pressure of a hundred weight without change of shape.

When the dilatant material, such as shot or sand, is bounded by smooth surfaces, the layer of grains adjacent to the surface is in a condition differing from that of the grains within the mass. This layer can slide between the one succeeding it and the surface, causing much less dilatation than would be caused by the sliding of a layer within the mass. Hence, if two parts of the mass are connected by such a surface, certain conditions of strain may be accommodated by a streaming motion of the grains next the surface. Thus, if into a glass funnel partially filled with shot and held in a vertical position more shot be forced from below, the particles will flow up all around the sides—not rising in the centre as might have been thought.

As the foot presses upon the sand when the falling tide leaves it firm, that portion of it immediately surrounding the foot becomes momentarily dry. When this happens the sand is filled, completely up to its surface, with water raised by capillary attraction. The pressure of the foot causes dilatation of the sand, and so more water is required. This has to be obtained either by depressing its level against the attraction or by drawing it through the interstices of the surrounding sand. As this latter requires time, for the moment the capillary forces are overcome, and the surface of the water is lowered below that of the sand, leaving it dry until a sufficient supply has been obtained from below, when it again becomes wet. On raising the foot we generally see that the sand under and around it becomes wet for a little time. This is because the sand contracts when the distorting forces are removed, and the excess of water escapes at the surface.

In referring to the results which might be expected to follow from a recognition of the property of dilatancy, the author said that it places a hitherto unknown

mechanical contrivance at the command of those who would explain the fundamental arrangement of the universe, and one which seems to promise great things besides possessing the inherent advantage of great simplicity. He then proceeded to explain, in a general way, how bodies in such a medium would—in virtue of the dilatation caused in the medium—attract each other at a distance, with a force depending on the distance, which might well correspond with the force of gravitation. Further, owing to the existence of a region close to the body in which the density varies several times from maximum to minimum, the mutual force might undergo a change from attraction to repulsion, and this more than once as the bodies approach—a condition which seems to account for cohesion and observed molecular force far better than any previous hypothesis.

The transmission of distortional waves becomes possible if the medium be composed of small grains with large grains interspersed. The separation of two such sets of grains leads to phenomena closely resembling the phenomena of statical electricity. The susceptibility of such a medium for a state in which the two sets of grains are in conditions of opposite distortions may explain electrodynamic and magnetic phenomena, while the observed conducting power of a continuous surface for the grains of a simple dilatant medium closely resembles the conduction of electricity.

2. *On Calculating the Surface Tension of Liquids by means of Cylindrical Drops or Bubbles. By* Professor G. Pirie, *M.A.*

The author asserted that surface tensions are found only approximately and with difficulty by measuring the dimensions of round drops. He suggested that cylindrical drops should be used. He worked out the theory and described experiments of verification.

---

3. *On the Surface Tension of Water which contains a Gas dissolved in it. By* Professor G. Pirie, *M.A.*

The object of the experiments was to discover if water, which holds a gas in solution, has a different surface tension from water which holds no gas; and if it has to discover the law according to which increasing quantities of gas absorbed affect the capillarity.

It was found that the surface tension is not measurably affected by those gases which, like air and carbonic acid, are not absorbed in sufficient quantities to affect markedly the specific gravity. A table of values of the specific cohesion was given for different quantities of two gases which are absorbed in large quantity.

4. *Thermodynamic Efficiency of Thermopiles.*[1] *By* Lord Rayleigh, *D.C.L., LL.D., F.R.S.*

---

5. *On the Measurement of the Intensity of the Horizontal Component of the Earth's Magnetic Field.*[2] *By* Thomas Gray, *B.Sc., F.R.S.E.*

The general principle of the method adopted was that of Gauss, with these modifications. In the deflection experiment the magnetometer needle was made so short that in the calculations it could be assumed without sensible error to be of zero length, and two deflectors were used simultaneously. The deflectors were placed one on each side of the magnetometer needle, with their axes in a line at right angles to the magnetic meridian; and in position for deflecting the needle the direction of the line passing through the centres of the deflectors and the magnetometer needle, were: first, the magnetic meridian, and second, a line at right angles

[1] Published in *Phil. Mag.* Oct. 1885.
[2] Published in *Phil. Mag.* Dec. 1885.

to it. The author pointed out that this mode of procedure leads to two equations which suffice for the determination of the horizontal component of the earth's magnetic field, and also of the effective length of the deflector. In these equations he also showed that the length of the deflector entered as a minus term in the one and plus in the other, and thus rendered the observations highly sensitive to possible errors in that term, and enabled a good estimate of the effective length of the different deflectors to be had. Apparatus was described by which the whole cycle of observations, both for this and the oscillation experiment, might be obtained without the necessity of handling the deflector magnets.

The effects of the various corrections on the value of 'H' derived from the equations were discussed. Such of the errors as were sensible had been made the subject of direct experiment, and their effect allowed for in the table of values of 'H' given in the paper and quoted below.

As the observations necessary for a determination of 'H' by this method extend over such a time as may make the diurnal variation sensible, and further to guard against the readings being vitiated by undetected magnetic storms, a magnetic vibrator was kept going throughout the time of the experiment, and its period taken from time to time as might be found necessary.

6. *On Atmospheric Electricity.*[2]

By Professor C. Michie Smith, *B.Sc.*, *F.R.S.E.*

The commonly accepted opinion, that during fine weather the air potential is always positive, is not accurate for Madras. There it is found that with a dry land wind (*i.e.*, a westerly wind) the potential of the air is usually negative during several hours of the day. In the early morning, and up to about 9 A.M., the potential is usually positive, then it becomes negative, reaching a maximum between 10 and 11 A.M., and continues negative till the sea breeze sets in in the

[1] Corrected to noon for diurnal variation.

[2] Published in full in *Phil. Mag.* Nov. 1885.

afternoon. During the prevalence of land winds there are frequent local showers, but these are evidently not the cause of the negative readings. Negative readings are never obtained in fine weather, except when the wind is westerly, and not even then, unless the ground is dry. A shower of rain, which cools the ground, makes the succeeding readings positive for some hours. A marked feature during the prevalence of land winds are the great clouds of dust which fill the air, and it seems probable that there is some connection between these dust clouds and the negative electrification of the air.

7. *Molecular Distances in Galvanic Polarisation.*[1] *By* Professor J. LARMOR, *M.A.*

It has been shown, principally by Helmholtz ('Wissen. Abhand.' Vol. I. Galvanismus, and Faraday Lecture, 'Journal of the Chemical Society,' 1882), that polarisation involves a condensing action on the surface of the metallic electrodes. The particles, say of the cation, which exist in the electrolyte in a state of temporary dissociation, are drawn towards the cathode by the electromotive force till further approach is prevented by chemical forces. Thus along the surface of the cathode we obtain a sheet of positively charged cation molecules, which are in an equidistant arrangement on account of their mutual repulsion; and opposite to each on the material of the electrode there is the equal and opposite charge drawn there by electrostatic induction. This double sheet is equivalent to a condenser.

Kohlrausch and Helmholtz measured the charge required to produce a given polarisation difference of potential, and therefrom estimated the thickness of this double layer.

Lippmann ('Comptes Rendus,' 1882) determined the surface energy of the charge for unit area from the variation of the capillary constant of a mercury electrode; and thereby gained an estimate in agreement with the above.

We should expect that the capacity of the double layer per unit surface would remain constant until the distance between contiguous cation particles became of the same order as the thickness of the double layer, *i.e.*, until the contiguous particles began to feel one another's chemical forces, and be influenced thereby. An examination of Lippmann's results shows this constancy of capacity to a very close degree for a range of about a volt. We may, accordingly, conclude that with his acidulated water polarised to a volt the particles of the polarisation layer have just become so numerous as to be in chemical contact with one another. This leads to a third estimate of a molecular distance which we find to agree with the two former.

The first estimate is based on the absolute electrostatic measurement of the charge; the second on the measurement of a surface tension; the third on the absolute electro-chemical equivalent of the electrolyte. The complete agreement of three estimates founded on physical constants so various and of so different orders of magnitude, is strong evidence of the validity of this method of interpreting the phenomena of polarisation.

They are all in satisfactory agreement with the estimates of Sir W. Thomson and others from different considerations ('Nature' 1870, 'Appendix F, Thomson and Tait's Natural Philosophy,' part ii.), and give an average result of about one 10^{-10} metre, more or less.

---

8. *On the Employment of Mance's Method for eliminating the Effects of Polarisation, to determine the Resistance of the Human Body. By* Dr. W. H. STONE, *M.A.*

The author commenced by stating that he had given a similar paper at the Southport meeting of the Association, in which it was noted that the electrical resistance of the human body was surprisingly less than that usually given, even by such authorities as Rosenthal, in Germany, and Dolbear, in America. He had

[1] See *Phil. Mag.* Nov. 1885.

shown that this was due to imperfect contact through the insulating skin. By immersing the extremities in saline solutions, and using large leaden electrodes, this initial error was eliminated, and a fair approximation to the real value obtained. But additional difficulties at once presented themselves; firstly, in that the living body acts as a secondary battery, and sets up very appreciable counter-electromotive force; secondly, that it has considerable electrostatic capacity, and acts to some extent as a condenser.

The former of these might be minimised by alternating momentary contacts with a reversing key, but, even thus, later readings were always somewhat higher than the earlier, giving a resistance compounded indefinitely of real resistance and polarisation. The use of alternate currents from a small induction coil on Kohlrausch's system, substituting a telephone for the galvanometer, an extremely elegant method, had occupied him for a year, but unfortunately it gives too low a result, probably from condenser action, and from the fact that a current rapidly reversed never actually traverses a very imperfect conductor like the human body, but only charges and discharges it in layers or segments.

Two opposite sources of error seem thus to be indicated, a condenser action spuriously lowering the reading, especially with alternate currents of high tension, and a polarisation action fallaciously raising it. The problem of ascertaining the amount of each of these was difficult. It had struck him, however, that the human body in many respects resembled a faulty submarine cable, in being at once a conductor, a condenser, and an electrolyte. He therefore, on the advice of Mr. Latimer Clark, adopted a method employed by Sir Henry Mance, on the Persian Gulf cables, and described before the Society of Telegraph Engineers, on May 8, 1884. It consisted in suddenly shifting the proportional coils of a specially constructed Wheatstone bridge (which was exhibited), and rapidly taking a fresh reading under the changed conditions. The values both of proportional coils and readings were then cross-equated so as to eliminate adventitious, and only retain intrinsic resistance. This method answered well, and gave results infinitely more concordant than any previously tried. For instance, two consecutive readings thus corrected gave 1,009 ohms and 1,007·8, a difference of less than one in 500, which was as near or nearer than could be expected in physiological electricity. He hoped thus to have overcome his first difficulty, and was endeavouring to meet those of measuring electrostatic capacity and opposite E. M. F. He already had roughly determined that the healthy body had a charging power as a secondary battery of about one volt or an ordinary Daniel cell, and he believed the chemical decomposition of tissue thus indicated was sometimes, especially in cases of rheumatic sciatica, the cause of the cure which frequently, indeed almost invariably, ensued.

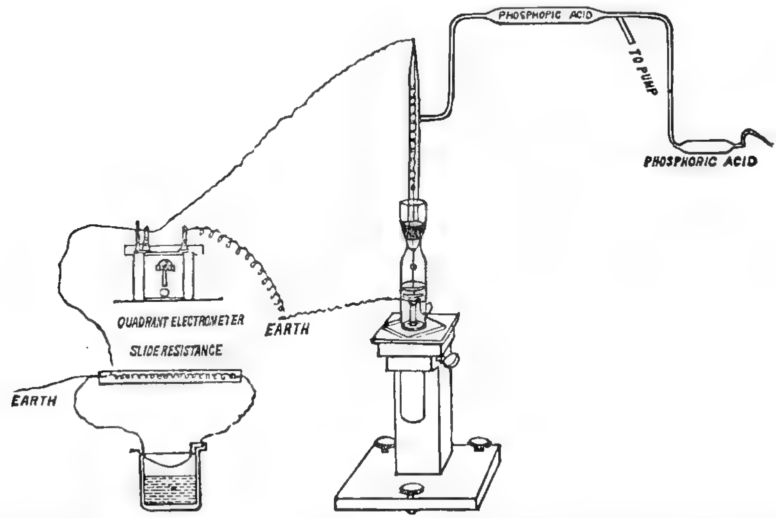
---

9. *On Contact Electricity in Common Air, Vacuum, and different Gases. By* J. T. Bottomley, *M.A., F.R.S.E.*

The discussion at the British Association meeting at Montreal last year on the seat of electromotive force in the voltaic cell, the paper of Professor O. Lodge which resulted from that discussion, and the subsequent discussion at the Society of Telegraph Engineers, must have brought forcibly before the minds of those interested in the subject the extremely unsatisfactory state of our experimental knowledge on some of the fundamental questions relating to contact electricity. Foremost among these, perhaps, is the question of the behaviour of various metals as to Volta contact effect in air and vacuum, and in gases different from common air. I have undertaken a series of experiments on this subject, and have already obtained some definite results; although the experiments which I have made up to this time are only to be considered as preliminary to a fuller inquiry.

The apparatus which I am using is shown in the diagram. The lower of the two plates to be experimented on is supported in the vacuum chamber by a small stand with a glass pillar, and the electrode from this plate passes through the side of the chamber, hermetically sealed into it. The upper plate is hung from the top

by a long platinum spiral, the upper end of which is also hermetically sealed into the glass. To the lower end of the spiral is attached a long hook, which carries the lower plate, and at the junction of the spiral with this hook there is a small globe of soft iron. It is by means of this small soft iron globe, and a magnet applied outside the tube, that the upper plate is lifted from the lower plate. The nature of the vacuum chamber and its connection to the pump will be readily



understood from the diagram. The final adjustment of distance between the two plates when at their nearest is done at the top of the tube by heating it and drawing out the glass carefully, or else letting it fall in till the adjustment is satisfactorily made. The branch tube on the right-hand side of the diagram, which is shown sealed off, is used for supplying gases to the apparatus. A small part only of the drying and purifying apparatus is shown in the diagram.

For determining the value of the Volta contact effect, I have used the quadrant electrometer and the compensation method of Sir William Thomson. The Daniell's cell and slide resistance and the connections are shown in the figure. The method is so well known that it need not be described here. It was given in 'Nature,' April 14, 1881, and has also been described in the paper of Professor O. Lodge, which was printed in the British Association Reports.

The plates which I have used are zinc and copper discs, a little larger than a shilling. Testing them first with full air-pressure, I found that the Volta contact difference was rather over 0·74 volt; which is as nearly as possible what has been found by previous experimenters, and by myself experimenting a few weeks ago with Sir William Thomson's old contact apparatus.

The air was then very carefully exhausted, the exhaustion being maintained for two days, and finally made exceedingly good with two and a half hours work at the pump just before testing. The pressure during the testing was not greater than, and was probably much less than $\frac{1}{523}$ mm. of mercury, or 2·5 M ($2\frac{1}{2}$ millionths of an atmosphere). The electrical test was then applied, and the value of the Volta contact effect was found to be *exactly the same as before,* a little over 0·74 volt. The final test, however, consisted in allowing the air to come back into the apparatus, and then testing electrically. This was done by breaking the point of the sealed tube to the right of the diagram; and as the air entered the electrometer test was rapidly applied. So far as the sensitiveness of the testing apparatus goes, there was absolutely no change in the Volta contact difference.

My experiments, therefore, are absolutely contradictory, so far as they have gone, to those of Dr. W. von Zahn, quoted by Professor Lodge, who experimented in a high vacuum and found the Volta effect to be diminished, and to be represented by a potential difference of only half a Daniell.

I have also experimented on hydrogen and oxygen gases in this apparatus in a way precisely similar to that described above. The chamber was very carefully exhausted, and the Volta contact effect tested with the electrometer. Hydrogen was then admitted, and while it was entering, which it was forced to do slowly, the electrical testing was repeated several times.

A second and a third exhaustion were made, and hydrogen admitted a second and a third time.

The same was subsequently done with oxygen, except that it was, of course, sufficient to admit the oxygen a single time. The result of my investigation, so far as it has gone, is that the Volta contact effect, so long as the plates are clean, is exactly the same in common air, in a high vacuum, in hydrogen at small and great pressure, and in oxygen. My apparatus, and the method of working during these experiments, was so sensitive that I should certainly have detected a variation of 1 per cent. in the value of the Volta contact effect, if such a variation had presented itself. To do away with all question as to the dependence of the Volta effect on 'ancient air sheets,' I propose to modify my apparatus by making the vacuum chamber much longer, and finally of combustion tubing. I shall then apply great heat to the plates while they are contained in a vacuum as high as I can command. If then there be any ancient air-sheets existing, they must either be driven off or else absorbed into the plates. If any gas be driven off, it will be removed by the pump. The plates will then be tested when they have perfectly cooled, and the value of the contact difference determined. That being done, the atmosphere air or some other gas will be admitted, and the contact difference will be again determined. The effect of the presence of the atmosphere or other gas will, I think we may safely suppose, be thus ascertained.

In conclusion, I have to express my indebtedness to Mr. J. Rennie, assistant to the Professor of Natural Philosophy in the University of Glasgow, for most valuable aid during my investigation.

---

10. *On a Specimen of almost Unmagnetisable Steel.* *By* J. T. Bottomley, *M.A., F.R.S.E.*

The author has examined a specimen of steel presented to Sir William Thomson by Mr. R. R. Eadon, of the firm of Moses Eadon & Sons, Sheffield. This steel is made under Hadfield's patent, and contains 15 per cent. of manganese, and one side of the specimen bar has been polished, and shows that the steel is capable of taking a very high finish. The present specimen has probably a tensile strength of forty-five tons to the square inch. To test it magnetically, the bar was first touched with steel magnets, and such preliminary trials seemed to show that the magnets had not the slightest effect upon it. It was then placed between the poles of a powerful Rhumkorf electro-magnet, which was excited by forty large tray Daniells, arranged in fours for quantity and ten in series; and the process for magnetising which is always used in the Glasgow University laboratory, and which is very satisfactory, was proceeded with. It was very astonishing to find the bar of steel absolutely unaffected by the electro-magnet, so far as could be perceived by the hand.

After magnetisation the bar was carefully tested by the magnetometer method, a mirror magnetometer being used for the purpose. The weight of the bar is 192·09 grammes, its length is 14·29 centims, it is of square section, and is 1·5 centim thick. The effective length of the bar as a magnet was estimated at 10 centims. The magnetometer determination gave for the magnetic moment

$$\mu = 2{\cdot}55 \text{ c.g.s.}$$

Dividing by the weight of the bar we find for the magnetisation per gramme of this specimen of steel, 0·013 c.g.s.

To compare this with other specimens of steel we find in many specimens that magnetisation of 40, 50, or even 60 c.g.s. per gramme can be obtained. In some specimens as much as 90 or even 100 c.g.s. per gramme has been obtained.

P.S. The author has been informed that Dr. Hopkinson has already experi-

mented on steel containing manganese, and has obtained similar results. He has not, however, seen Dr. Hopkinson's figures, and is unable to compare his own results with them.

11. *On the Cooling of Wires in Air and in Vacuum.* *By* J. T. Bottomley, *M.A., F.R.S.E.*

This paper gave a brief account of recent experiments on radiation of heat from the surface of metallic wires in air and in vacuum. A preliminary paper on this subject was communicated to the British Association at its meeting last year. Since that time the arrangements for experimenting have been greatly improved, and further results have been obtained. The object is to determine in absolute measure the loss of heat from the surface of small wires of various materials, both uncovered and covered with various coatings, the wires being surrounded with different gases at various pressures down to the very lowest.

The chief experimenters on this subject in recent times have been Kundt and Warburg, and Mr. Crookes. My method of experimenting, which is very different from that of other experimenters, consists in passing a current of known strength through the wire under examination, and determining the increase in resistance of the wire due to heating of the currents when the wire has assumed a permanent temperature with the given current passing through it. When the temperature of the wire has become constant, the heat generated by the current (which can be calculated in absolute measure) must be equal to that emitted at the surface of the wire, plus that lost at the ends of the wire. The temperature of the wire at the moment is also ascertained from its resistance (as was done by Siemens in his experiments in resistance of platinum wire at different temperatures, 'Proc. R.S.' vol. xix. p. 443); and the emissivity of the surface of the wire can thus be determined in absolute measure.

My recent experiments have been directed to the determination of emissivities in very high vacuums. Using a Sprengel pump with five fall tubes, and a McLeod gauge of improved construction, due to Mr. C. H. Gimingham, I have obtained and measured a vacuum with air pressure as low as $\frac{1}{30}$ M (one thirty millionth of an atmosphere). The wire with which I am experimenting at present is a platinum wire half a metre long and 0·04 c.m. in diameter. It is contained in a glass tube about 0·6 c.m. internal diameter.

A table of emissibilities per metallic surface has not yet been completed, but one result obtained with a high vacuum may be quoted. On passing a current of 1·18 amperes through this wire with full air pressure, the permanent temperature obtained by the wire was 75° C., the temperature of the room at the time being 15·2 C. On exhausting down to $\frac{1}{19}$ M ($\frac{1}{19} \times 10^{-6}$ atmosphere) and passing the same current, the wire became heated to a good red heat.

FRIDAY, SEPTEMBER 11.

The following Papers and Reports were read:—

1. *On Kinetic Theories of Matter.* *By* Professor A. Crum Brown, *M.D., F.R.S.*

2. *On Kinetic Theories.* *By* Professor G. D. Liveing, *M.A., F.R.S.*

3. *On Thermal Effusion and the Limiting Pressure in Polarised Gas.* *By* G. Johnstone Stoney, *LL.D., F.R.S.*

4. *On a Law concerning Radiation. By* Professor SCHUSTER, *Ph.D., F.R.S.*

5. *On Boltzmann's Theorem. By* Professor W. M. HICKS, *M.A., F.R.S.*

It has always seemed to me that one of the strongest objections to Boltzmann's theorem lay in the supposition that the mean energy of any kind of vibration of any atom must be equal to that of translation in any direction, and therefore capable of unlimited increase. It is not difficult to conceive of systems where this cannot be true, as, for instance, a rigid spherical shell with a vortex ring inside. In this system the internal energy may be made to vary within certain limits, but cannot possibly be increased beyond a certain amount. The fact seems to be that Maxwell's theorem and Boltzmann's extension do not necessarily correspond to the actual state, but are only proved to give *possible* distributions of energy which are permanent. In any case, however, even if we assume the law of distribution of momenta given by them to be true, I can see no reason to justify us in assuming, either that all values of any momentum from $-\infty$ to $+\infty$ are possible, as is done in Watson's proof, or even that all values consistent with the equation of energy are possible, as is done in Maxwell's proof. If in Watson's proof all the non-existent states are left out of account, the *form* of solution is unaltered, but the energy will no longer be equally distributed amongst the co-ordinates. In this case, therefore, there is no difficulty in accounting for the ratio of the two specific heats in different cases, although it is not possible to predict it until the general constitution of the atom is known. Maxwell's proof takes account of the whole history of a molecule, and not merely of what happens at a collision as in Watson's. But it cannot be generally true that all states consistent with the equation of energy are possible. For instance there may be geometrical relations which prevent it, but which do not appear in that equation; as for example in a system of mutually attracting spheres. The equation of energy would permit of the infinite velocities due to an infinitely near approach of the centres of two spheres, a state which cannot exist owing to the finite size of the spheres. Another case is where the integrals of the equations of motion of the atom introduce relations between different momenta, as, for example, where part of the system consists of connected gyrostats.

6. *The Rate of Explosion of Hydrogen and Oxygen. By* H. B. DIXON, *M.A.*

The author has continued his experiments on the velocity of explosion of electrolytic gas. His results confirm those of Berthelot that the explosion is propagated at a constant velocity which is independent of the diameter of the tube. With a tube 100 metres long the mean of ten experiments gave a velocity of 2,819 metres per second, with a probable error of four metres. This velocity is in close agreement with the mean velocity of translation of the steam molecules produced in the reaction calculated on the supposition that all the heat produced is retained in the steam. The calculated velocity is 2,831 metres per second.

7. *Report of the Committee for constructing and issuing practical Standards for use in Electrical Measurements.*—See Reports, p. 31.

8. *Report on Electrical Theories. By* Professor J. J. THOMSON, *M.A., F.R.S.*—See Reports, p. 97.

9. *On Constant Gravitational Instruments for measuring Electric Currents and Potentials. By* Professor Sir W. THOMSON, *LL.D., F.R.S.*

These instruments, the author stated, were parts of two series of electric measuring instruments, for current and potential, which he was now working out. In the two current instruments—the milliamperemeter and the hecto-amperemeter—

the mode of effecting the measurement was founded on Faraday's law, according to which a ferro-magnetic mass placed in a variable magnetic field experiences forces tending to make it move from places of weaker to places of stronger force. The essential parts of the milliamperemeter are shown in the sketch diagram, fig. 1. It consists of an electro-magnetic coil, fixed with its axis vertical, and a little cylindrical mass of soft iron hung from one end of a light balanced lever so as to be free to move up and down in a circular arc, deviating but little in its middle and at its two ends from the axis of the coil.

The measurement is given by the deflections indicated on a scale by the end of

Fig. 1.

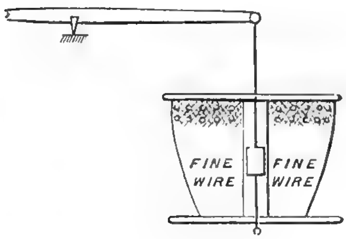


Fig. 2.

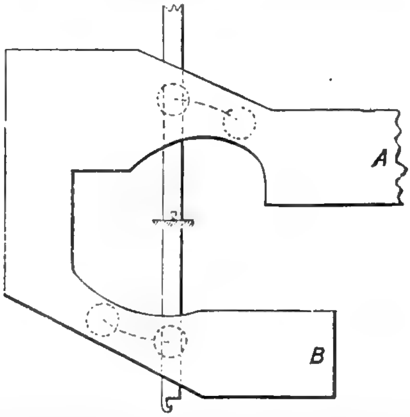

the balanced lever, when a weight of known amount is hung on the ring below the iron mass. To screen the iron from the effects of the earth's magnetism the coil is enclosed in an iron box.

In the hecto-amperemeter the variable magnetic field is obtained by a suitable disposition of the metallic conductor conveying the current to be measured. The conductor may be taken as consisting of two thick copper plates, shaped each according to the sketch, fig. 2, supported in a vertical position parallel to each other, say one centimetre apart, and metallically connected at the place indicated by B. At A is fixed a suitable electrode. The course of the current is therefore from A to B, and from B across to and through the other plate to the part of it corresponding to A, which forms the other electrode. In this way, two similarly varying magnetic fields are produced, and the balanced lever, capable of motion in a plane situated midway between the plates, carries two masses of iron, one in each field. In other respects, the instrument is similar to the milliamperemeter.

The electrometer consists of an air condenser with one of its plates capable of a to-and-fro motion so as to vary the capacity of the condenser.

The fixed brass plates are supported so as to be accurately parallel to each other and in metallic connection, while they are thoroughly insulated from the case of the instrument. The movable plate is of aluminium, and is supported in a vertical position on a knife edge; the plane of its motion being parallel to the fixed plates and situated midway between them. The upper end of this movable plate has a fine prolongation which serves as a pointer for indicating the deflections on the scale of the instrument, and at its lower end is fixed a knife edge having its length perpendicular to the plane in which the plate moves.

When the fixed and movable plates are connected respectively to two points of an electric circuit between which there exists a difference of potential, the movable plate tends to move so as to augment the electrostatic capacity of the instrument, and the magnitude of the force concerned in any measurement is proportional to the square of the difference of potential by which it is produced. In the use of the instrument this force of attraction is balanced by the horizontal component of a weight of any convenient amount hung on the knife edge at the bottom of the movable plate.

10. *On a method of multiplying Potential from a hundred to several thousand Volts. By* Professor Sir WILLIAM THOMSON, *LL.D., F.R.S.*

The method described by the author was to arrange in series a number n of condensers, where n is the number indicating the required multiplication. A terminal is connected to the junction between each pair of adjacent condensers. This series of $n+1$ terminals is conveniently placed so that by a suitable mechanism a pair of movable electrodes, between which a known difference of potentials exists, may be brought successively and repeatedly, at short intervals of time, into contact with each pair of adjacent terminals in the series, moving always in the same direction along them. In this way the difference of potentials established between the two end terminals of the series of condensers is n times the known difference of potentials between the movable electrodes.

---

11. *On a form of Mercury Contact Commutator of Constant Resistance for use in adjusting Resistance Coils by Wheatstone's Bridge, and for other purposes. By* Professor J. VIRIAMU JONES.

The author was first led to consider commutators of the kind described by two needs: (1) In simple experiments on the induction of electric currents by the solution of a current in a magnetic field, it was desirable to substitute mercury contacts for the brass brass and copper copper contacts of the simple split ring commutator, and (2) for experiments on the resistance of electrolytes it is necessary to continue rapidly reversing the current without altering the resistance of the circuit.

The simple commutator with mercury contacts consists of two co-axal, parallel, and equal split rings of copper, the lines of split being parallel to one another, and the halves being cross-connected. The split rings are supported on ebonite discs. If it is desired to convert a continuous current into an alternating current without change of resistance in the circuit, it is only necessary to add to the above simple commutator two other (unsplit) rings of copper properly connected and turning in mercury cups communicating with the terminals of the part of the circuit in which the current is continuous.

If more rapid commutation is required, then by dividing the copper rings of the simple commutator into say six parts, and cross-connecting these, the current will be reversed six times in each revolution.

By means of eight discs, each carrying a copper ring divided into two parts, the lines of split in the first, fourth, fifth, and eighth, being all parallel and at right angles to the lines of split of the second, third, fifth, and sixth, which are also all parallel, we may by proper connections change the direction of the current through two independent coils, then interchange the coils, and again reverse the direction of the current through the coils in their new position. Such a commutator, it will be perceived, is of great utility in adjusting resistance coils by Wheatstone's bridge.

12. *On Slide Resistance Coils with Mercury Contacts. By* Professor J. VIRIAMU JONES.

---

13. *On the relative Merits of Iron and Copper Wire for Telegraph Lines. By* W. H. PREECE, *F.R.S.*

Copper is gradually replacing iron for aërial telegraphs, owing to its greater durability in the atmosphere; but its greater cost has led to the use of smaller-sized wires. This can be done without detriment to the economy of the line, for the resistance of copper, as compared with iron, varies very nearly inversely as its price per ton, and hence the cost per mile remains about the same. Hitherto only short lengths have been erected in smoky towns and through districts where

chemical industries filled the air with gases destructive to iron wires; but the Post Office Telegraph Department has recently erected a No. 14 copper wire, ·080 in. in diameter, weighing 100lb. per mile, all the way from London to Newcastle, 278·08 miles in length, and it became desirable to measure very accurately its electrical elements, so as to see if it possessed, as was anticipated, any marked advantage as a telegraph line over the galvanised iron wires hitherto used.

There were two series of experiments made. In the *first* series the relative electrical condition of the two kinds of wires was determined, and in the *second* series their relative rates of working.

The first series was divided into two parts, the one consisting of tests made from Bishop Auckland to Teams, near Newcastle, a distance of 30·235 miles on the north side, and to Pierce Bridge, a distance of 9·172 miles on the south side, and the other consisting of tests of a section of line between Pierce Bridge and Baldersby Cross Roads, 26·7 miles in length. The poles carried ten wires. The tests were made in dry and favourable weather by Messrs. Kempe and Eden.

The electrostatic capacity of an aërial line is known to vary as

$$\log \frac{4h}{d}$$

where h is the height of the wire above the ground, and d its diameter. Now, the average height of the copper wire on the sections between Bishop Auckland and Teams and between Pierce Bridge and Baldersby Cross Roads is 23 feet, and that of the iron wire (on a lower arm of the pole) 22 feet, their diameters being ·080 in. and ·171 in. respectively. We have, therefore, for copper wire

$$\log \frac{4h}{d} = \log \frac{4 \times 23 \times 12 \times 1000}{80} = 4{\cdot}1398791,$$

for iron wire

$$\log \frac{4h}{d} = \log \frac{4 \times 23 \times 12 \times 1000}{171} = 3{\cdot}7906678,$$

and

$$\frac{3{\cdot}7906678}{4{\cdot}1398791} = {\cdot}916 \text{ nearly,}$$

which makes the capacity of the copper wire to be $100 - 91{\cdot}6$, or 8·4 per cent. less than that of the iron wire. This result agrees pretty closely with the mean value of the differences of capacity obtained by actual measurements on these sections—viz., 9·1 per cent.

For the Bishop Auckland-Pierce Bridge section we have:—

For copper wire

$$\log \frac{4h}{d} = \log \frac{4 \times 21 \times 12 \times 1000}{80} = 4{\cdot}1003705.$$

For iron wire

$$\log \frac{4h}{d} = \log \frac{4 \times 20 \times 12 \times 1000}{171} = 3{\cdot}7492751$$

and

$$\frac{3{\cdot}7492751}{4{\cdot}1003705} = {\cdot}914$$

making the capacity of the copper wire to be $100 - 91{\cdot}4$, or 8·6 per cent. less than that of the iron, whilst the actual value was found to be 9·7 per cent. The differences between the calculated and the experimental values are probably due to the influence of trees, buildings, &c., which cannot be allowed for theoretically. These measurements were made when the other wires on the poles were left insulated. The effect of having all the other wires to earth when the capacity of any one wire was measured was very marked. Thus, on one wire the capacity was increased from ·352 to ·451 microfarad, or 22 per cent.

As regards the induction between wire and wire the effects obtained were very slight, though their actual value was determined with comparative accuracy.

The second series of experiments were conducted between London and New-

castle, and were designed, as stated above, to test the working efficiency of the copper wire as compared with iron wires. They were conducted by Messrs. Chapman and Eden.

Copper shows a very decided superiority over iron, the speeds being as follows:—

	Copper	Iron
Simplex working .	414 . .	345 words per minute.
Duplex " .	270 . .	237 " "

It is anticipated that the superiority of copper over iron indicated by these experiments will have a beneficial and economical influence on our telegraph system, and that its extended use will enable us not only to work better, but to dispense with intermediate repeaters in many cases where, on long lines, they are now necessary.

The most interesting point, however, in connection with these experiments is that they apparently prove that the superiority of copper is not simply due to its smaller electrostatic capacity and resistance, but that it is more susceptible to rapid changes of electric currents than iron; for when the resistance and capacity of the copper and iron wires were equalised by the insertion of resistance coils and condensers, the speed on the former was not thereby diminished. Possibly the magnetic susceptibility of the iron is the cause of this. The magnetisation of the iron acts as a kind of drag on the currents. It is well known that telephones always work better on copper than on iron wires, doubtless for the same reason.

These experiments also show the high speed of working that is now attained by the Post Office authorities with the Wheatstone automatic apparatus. The following table gives an interesting *résumé* of the different stages of the progress made, and its rate of growth:—

1877 .	. 80 words per minute.	1881 .	. 190 words per minute.
1878 .	. 100 " "	1882 .	. 200 " "
1879 .	. 130 " "	1883 .	. 250 " "
1880 .	. 170 " "	1884 .	. 350 " "

SATURDAY, SEPTEMBER 12.

The following Papers were read:—

1. *On Orthoptic Loci. By the* Rev. C. Taylor, *D.D.*

An *orthoptic point* with reference to a curve is a point at which it subtends a right angle, that is to say, it is the point of concourse of a pair of orthogonal tangents. The *orthoptic locus* of a curve is the locus of intersection of pairs of tangents drawn to it at right angles. It is proposed to determine the *order* of the orthoptic locus of a curve of given *class.*

The order of the locus is determined when its complete intersection with any straight line, for example the *line at infinity,* is known.

The tangents drawn from any point on the line at infinity are parallel, and in general cannot be regarded as including any finite angle. But the case is different with lines drawn from one of the circular points I or J.

Any two such lines, IO and IO′, may be regarded as including any angle whatsoever, since all the circles that can be drawn through any two points O and O′ pass through I.

The orthoptic locus of an ellipse (or hyperbola) is a circle, as De la Hire showed just two centuries ago (Paris, 1685). This may be demonstrated as follows:— From I (or J) one pair of tangents and one only can be drawn to the ellipse, and they may be regarded as intersecting at right angles. Hence I and J being single points on the locus and being its only points at infinity, the locus is a circle.

The orthoptic locus of the cardioid, a curve of the third class, is known to consist of a circle and a bicircular quartic, together making up a *tricircular sextic*. Such likewise must be the locus for a curve of the third class in general, since three tangents can be drawn to it from I (or J), and they may be regarded as intersecting two and two at right angles. Consequently I and J are threefold points on the locus: and they are its only points at infinity.

If the original curve be of class n, then from I (or J) n tangents can be drawn to it, and these can be taken in $n\frac{(n-1)}{2}$ ways in orthogonal pairs. This being therefore the order of each of the circular points on the orthoptic locus, the order of the locus is $n(n-1)$.

The order of the locus is apparently reduced when the original curve *touches the line at infinity*. Thus, in the parabola the line at infinity may be regarded as at right angles to the second tangent that can be drawn from any point upon it. Every such point therefore belongs to the locus, and the remainder of it when the line IJ is subtracted is a straight line not passing through the circular points, evidently the polar of the focus S, since SI (or SJ) is a tangent at right angles to itself. In like manner the reduction for a curve of class n which touches the line IJ in r points may be estimated.

By the same kind of argument it may be shown that if pairs of tangents be drawn to two curves of class m and class n respectively, each to each, their locus of intersection will be a curve of the order $2mn$, passing mn times through the circular points. The *pedal* of a curve of class n is therefore an n-circular $2n$-ic. That of an ellipse in general a bicircular quartic.

It remains to explain the apparent reduction of the order of the pedal with respect to a *focus*.

Taking for example the case of the ellipse, and eliminating between the equations:—

$$y-mx=\sqrt{(b^2+m^2a^2)}$$

and

$$my+x=\sqrt{(a^2-b^2)}$$

we have

$$(1+m^2)(x^2+y^2-a^2)=0$$

The factor $1+m^2$ equated to zero gives the directions of I and J, the tangents from which intersect in opposite pairs at the foci. The perpendicular from a focus S to the tangent SI is SI itself, which is accordingly a factor of the pedal, as likewise is SJ. But SI and SJ make up the *point-circle* at S. This factor corresponding to $1+m^2$ being rejected, the remainder of the pedal must be a circle, evidently that on the axis as diameter.

---

2. *On the Reduction of Algebraical Determinants.* *By* W. H. L. Russell, *F.R.S.*

The following method, it will readily be seen, is applicable to all determinants in which the constituents of every column are rational and entire functions of (x). Consider the determinant:—

$$\begin{vmatrix} a_1+b_1x+c_1x^2+d_1x^3, & a_2+b_2x+c_2x^2+d_2x^3, & a_3+b_3x+c_3x^2+d_3x^3, \\ a_4+b_4x+c_4x^2+d_4x^3, & a_5+b_5x+c_5x^2+d_5x^3, & a_6+b_5x+c_6x^2+d_6x^3, \\ a_7+b_7x+c_7x^2+d_7x^3, & a_8+b_8x+c_8x^3+d_8x^3, & a_9+b_9x+c_9x^2+d_9x^3. \end{vmatrix}$$

Divide the first, second, and third rows by $a_1\ a_4\ a_7$ respectively, and subtract the first row from the second and third rows, and the determinant becomes

$$\begin{vmatrix} 1+b'_1x+c'_1x^2+d'_1x^3, & a'_2+b'_2x+c'_2x^2+d'_2x^3, & a'_3+b'_3x+c'_3x^2+d'_3x^3, \\ 0+b'_4x+c'_4x^2+d'_4x^3, & a'_5+b'_5x+c'_5x^2+d'_5x^3, & a'_6+b'_6x+c'_6x^2+d'_6x^3, \\ 0+b'_7x+c'_7x^2+d'_7x^3, & a'_8+b'_8x+c'_8x^2+d'_8x^3, & a'_9+b'_9x+c'_9x^2+d'_9x^3, \end{vmatrix}$$

that is:—

$$\begin{vmatrix} a'_5+b'_5x+c'_5x^2+d'_5x^3, & a'_6+b'_6x+c'_6x^2+d'_6x^3, \\ a'_8+b'_8x+c'_8x^2+d'_8x^3, & a'_9+b'_9x+c'_9x^2+d'_9x^3. \end{vmatrix}$$

$$+\mu x\begin{vmatrix} b'_1+c'_1x+d'_1x^2, & a'_2+b'_2x+c'_2x^2+d'_2x^3, & a'_3+b'_3x+c'_3x^2+d'_3x^3, \\ b'_4+c'_4x+d'_4x^2, & a'_5+b'_5x+c'_5x^2+d'_5x^3, & a'_6+b'_6x+c'_6x^2+d'_6x^3, \\ b'_7+c'_7x+d'_7x^2, & a'_8+b'_8x+c'_8x^2+d'_8x^3, & a'_9+b'_9x+c'_9x^2+d'_9x^3, \end{vmatrix}$$

Where μ does not involve (x): by repeating the process we obtain two more minors and the determinant:—

$$x^3\begin{vmatrix} p, & a'''_2+b'''_2x+c'''_2x^2+d'''_2x^3, & a'''_3+b'''_3x+c'''_3x^2+d'''_3x^3, \\ q, & a'''_5+b'''_5x+c'''_5x^2+d'''_5x^3, & a'''_6+b'''_6x+c'''_6x^2+d'''_6x^3, \\ r, & a'''_8+b'''_8x+c'''_8x^2+d'''_9x^3, & a'''_9+b'''_9x+c'''_9x^2+d'''_9x^3, \end{vmatrix}$$

so that the original determinant is resolved into the sum of six minors of the form:—

$$\begin{vmatrix} A_1+B_1x+C_1x^2+D_1x^3, & A_2+B_2x+C_2x^2+D_2x^3, \\ A_3+B_3x+C_3x^2+D_3x^3, & A_4+B_4x+C_4x^2+D_4x^3, \end{vmatrix}$$

4. *A Theorem relating to the Time-moduli of Dissipative Systems. By* Lord RAYLEIGH, *D.C.L., LL.D., F.R.S.*

In the proceedings of the Mathematical Society for June 1873, it is shown that the times of vibration of a conservative system fulfil a stationary condition, so that the time of vibration in any normal mode would remain unaltered, even though the system, by the application of suitable constraints, be made to vibrate in a mode slightly different. It is pretty evident that a similar theorem must obtain for the time-moduli of the normal modes of a dissipative system, but a formal statement may not be useless.

The class of systems referred to is that of which the mechanical properties depend upon *two* functions, one being the dissipation function F, and the other *either* the kinetic energy T, *or* the potential energy V. As examples of the first case may be mentioned, the subsidence of the small motion of a viscous fluid contained in a fixed envelope, and of free electric currents in a conductor. On the other hand, in the distribution of heat in a thermal conductor, or of electricity in a cable, the undissipated energy is usually regarded as potential. The argument is almost exactly the same whichever case be contemplated; to fix ideas we will take the former.

By suitable transformation the two quadratic functions T and F may be reduced to sums of squares of co-ordinates, and these co-ordinates are consequently called normal. Thus:—

$$T=\tfrac{1}{2}\,[1]\,\dot\phi^2, +\tfrac{1}{2}\,[2]\,\dot\phi_2{}^2+\ \ldots$$
$$F=\tfrac{1}{2}\,(1)\,\dot\phi^2, +\tfrac{1}{2}\,(2)\,\dot\phi_2{}^2+\ \ldots$$

in which all the coefficients [1] . . . (1) . . . are positive.

The normal modes are those represented by the separate variation of the co-ordinates, and the corresponding differential equations are of the form:—

$$[s]\ddot\phi_s+(s)\dot\phi_s=0,$$

whence

$$\phi_s=\mathrm{P}e^{-pt}$$

where

$$p=(s)/[s]$$

If τ_s be the time-modulus, the time in which the motion is diminished in the ratio of $e:1$, $\tau_s=p^{-1}$.

Suppose now that by suitable constraints an arbitrary type of motion is imposed upon the system, so that $\phi_1=A_1\theta$, $\phi_2=A_2\theta$, . . . where A_1, A_2 &c. are given (real) coefficients. Then

$$T=\{\tfrac{1}{2}[1]A_1{}^2+\tfrac{1}{2}[2]A_2{}^2+\ \ldots\ \}\dot\theta^2$$
$$F=\{\tfrac{1}{2}(1)A_1{}^2+\tfrac{1}{2}(2)A_2{}^2+\ \ldots\ \}\dot\theta^2;$$

and the equation of motion

$$\frac{d}{dt}\frac{dT}{d\theta\cdot}\Big) + \frac{dF}{d\theta\cdot} = 0$$

gives as the solution $\theta \propto e^{-pt}$, whence

$$p = \frac{(1)A_1^2 + (2)A_2^2 + \ . \ .}{[1]A_1^2 + [2]A_2^2 + \ . \ .}.$$

It is evident that the value of p (and therefore of τ) is stationary when all but one of the coefficients A_1, A_2, &c., vanish, that is when the type coincides with one of those natural to the system.

From this theorem corollaries may be drawn as from the corresponding theorem for times of vibration. The greatest time-modulus can only be reduced by the application of constraint, and where the normal mode is difficult of calculation a good approximation to the greatest time-modulus may be had from a hypothetical type chosen so as not to deviate too widely from the real one. Any increase in T or diminution in F as a function of the co-ordinates entails in general an augmentation in all the time-moduli. In the case of free electric currents, already referred to as an example, this augmentation of time-moduli would result from the approximation of iron (treated as a non-conductor), or from an improvement (however local) in conductivity.

5. *On a new Polariser devised by Mr. Ahrens.* *By* Professor SILVANUS P. THOMPSON, *D.Sc.*

This prism consists of a tetragonal block of calc-spar, the square ends of which are principal planes of section of the crystal; the axis of symmetry of the prism being at right angles to the crystallographic axis. It is divided by two planes making an angle of about 36° with one another; their intersecting line lying across the middle of one of the end faces. These two planes divide the prism into three wedges which are united together by Canada balsam. The polarised field of vision has about 28° of angular aperture. The line of junction which traverses the end face is quite imperceptible when the prism is used as a polariser, though it interferes slightly with the field when the prism is used as an analyser. In the writer's opinion it is the best polariser hitherto designed.

6. *On a simple Modification of the Nicol Prism giving Wider Angle of Field.* *By* Professor SILVANUS P. THOMPSON, *D.Sc.*

This modification consists in reversing the obliquity of slope of the end-faces, making them incline about 5° instead of 45° with the crystallographic axis, and in cutting the crystal across in such a plane that the balsam film makes 89° with the new end faces, or about 94° with the crystallographic axis. This 'reversed' prism may have, externally, exactly the same form as the ordinary Nicol prism if cut from a longer piece of spar. If cut from a piece of the same proportions as an ordinary Nicol prism, the new prism will be somewhat shorter; but will have a slightly wider field. The 2 'reversed' prisms presented to the section have angular fields of 32° and 37° respectively. That of the ordinary Nicol is about 25° 30′. This method of construction may be looked upon as a compromise between the methods of Hartnack and of Nicol. It combines most of the advantages of the former with the cheapness of the latter.

7. *On some of the Laws which regulate the Sequence of Mean Temperature and Rainfall in the Climate of London.* *By* H. COURTENAY FOX, *M.R.C.S.*

The materials used in preparing this paper are the monthly temperature and rainfall for the Royal Observatory, Greenwich, from 1815 to the present time. They form a series of carefully recorded facts extending over the long period of

seventy years. In order to make practical use of this large mass of material, it was arranged in the following manner:—Taking out first all the Januaries, then the Februaries, and so on, I arranged each month, not in chronological order, but in the order, first, of its mean temperature, and afterwards of its rainfall. The same thing was also done for each meteorological season (winter consisting of the three months, December to February, and the other seasons in order).

In accordance with the principle which I had the pleasure of explaining to the British Association in 1879, and which is described at page 277 of the Report for that year, I divided each of these arranged lists as nearly as possible into five equal sections. Those referring to temperature are termed respectively, very cold, cold, average, warm, and very warm, and those referring to rainfall are named, very dry, dry, average, wet, very wet. We have thus a fair division of this long series of years, as regards the important characters of warmth and moisture. This simple arrangement is of the greatest utility in enabling us to generalise upon the mass of facts that have accumulated to our hand.

Taking out first all those months that were 'very cold,' there is no difficulty in writing down against them, in order, the character as regards mean temperature and rainfall of the months that came next after, and in saying how many of these latter were very cold, how many were cold, and so on, through the several sections of temperature and rainfall. Then, to ascertain the influence of high temperature, or of very dry or rainy weather, we take out all those months that were very warm, or very dry, or very wet, and proceed in the same manner. Supposing, for example, that we wish to inquire in what way great warmth in January affects the following month. We take all the instances (fifteen in number) within the last seventy years in which January was 'very warm.' Obviously there must be fifteen Februaries to be examined. We find that three of these were 'very cold,' none were 'cold,' five were of 'average' temperature, two were 'warm,' and five were 'very warm.' Therefore, as regards the *temperature* of February it is safest to say that the result is *indefinite*, because the three very cold and the five very warm ones too nearly balance each other to enable us to assert that there is a distinct tendency toward either side. But as regards the *rainfall* of these same Februaries, we find that seven of them were very dry, one was dry, two were average, three more were wet, and the remaining two were very wet. These facts exhibit a strong tendency for a very warm January to be followed by a dry February. Out of fifteen cases, seven Februaries were very dry against two that were very wet. The *probability*, therefore, of a very dry rather than a very rainy February may be conveniently expressed by the formula—7 to 2 out of 15.

Proceeding in the manner thus briefly indicated, it is remarkable what a harvest of interesting results promises to reward the inquirer. It is, indeed, surprising in how many cases the warmth or moisture of one month or season is discovered to be influenced by some unsuspected law of association with the month or season which it succeeds.

Omitting all those results which are of an ambiguous or indefinite character, I would venture to state the following definite propositions:—

1. A very cold spring tends to be followed by a cold and wet summer. The probability of a very cold summer is decidedly strong, being 6 to none out of 15,[1] and that for a very wet one is 5 to 1 out of 15.

2. A very cold summer tends to be followed by a cold autumn, the probability being 6 to 1 out of 14.

3. Very warm summers are prone to be succeeded by warm autumns, 5 to 1 out of 14.

So much for the influence of the seasons on those which come directly after them. Except in these three instances I perceive no definite law. Now let us see the apparent effect of one month upon another following it:—

4. In seven out of the twelve months we find that *very low* temperatures tend to be prolonged into the succeeding months. Thus, a very cold January gives a likelihood of a cold February, the probability being 4 to 1 out of 14; a very cold

[1] That is to say, of fifteen very cold springs, six were followed by very cold summers, and *none* by a very warm one.

April has a strong tendency to be followed by a cold May, 6 to none out of 13; a very cold June conduces to a cold July, 6 to 2 out of 13; and a very cold July to a cold August, 5 to none out of 13. A very cold August gives a remarkably strong probability of a cold September, 7 to none out of 14; a very cold September is succeeded by a cold October in the smaller ratio of 4 to 1 out of 13; and a very cold December tends to be followed by a cold January, 6 to 1 out of 14. It is noticeable that in three of these months, April, July, and August, the influence of cold is so strong that the facts were *without marked exception.*

In the other five months of the year I find no evidence that low temperature definitely affects the succeeding months. Meanwhile it is interesting to observe that of the seven which do show influence four are consecutive, namely, June, July, August, and September, the hottest four months of the year.

5. A very warm June has a strong probability to be succeeded by a warm July, 7 to none out of 13; and a very warm July by a warm August, 7 to none out of 14. A very warm August tends to be followed by a warm and wet September, the probability for each one of these events being identical, namely, 5 to none out of 15. It will be noticed that this proposition applies to the three consecutive summer months, and that the facts were without any marked exception.

6. The rainfall sequence of consecutive months and seasons appears to observe no definite rule, except in one striking case, which is as follows:—A very dry August is apt to be followed by a wet September, 7 to 1 out of 16. *Nowhere else* do we find a distinct tendency for a month or season to be of *opposite* character as regards warmth or moisture to that which it succeeds.

In addition to the foregoing, there are some instances in which the *temperature* of certain months appears to be related to antecedent conditions of *rainfall,* and *vice versâ.* Thus:—

7. In two months of the year the fact of their being *dry* is strongly followed by warmth in the next month. Thus a very dry June has a strong tendency for a warm July, 5 to none out of 15; and a very dry July for a warm August, 6 to none out of 13.

8. On the other hand, in three months of the year *abundant rain* gives likelihood of a warm month to follow. Thus a very wet January is followed by a warm February, 7 to 1 out of 13; a very wet March by a warm April, 4 to none out of 11; and a very wet April by a warm May, 5 to 1 out of 13.

9. The contrary of this occurs in two months—a very wet May being strongly followed by a cold June, 6 to none out of 14; and a very wet July by a cold August, 5 to none out of 13.

10. A very warm January is likely to be succeeded by a dry February, 7 to 2 out of 15.

It may naturally occur to ask—all these being instances in which a month or season is looked at in *one* character only—What are the results when they are examined with relation to the *combinations* of temperature and moisture? Do their characters, as warm and wet, cold and dry, warm and dry, cold and wet, show a tendency to influence the months following? We cannot so fully answer this question, because, in proportion as we define the character, we lessen the area of the observation. At the same time there are a few results that it may be worth while to adduce.

11. *Warm and Wet.*—If November be of this character (which has happened five times in the past 70 years), December will tend to be wet, 2 to none out of 5; so also a very warm and very wet December is likely to be followed by a wet January, 4 to 1 out of 6. But in January the same combination gives a probability of a warm February, 4 to 1 out of 8.

12. *Cold and Dry.*—If November have this character, the following December has a slight tendency to be dry, 2 to none out of 6. But a very cold and very dry December gives likelihood of a cold January, 3 to none out of 6.

13. *Warm and Dry.*—In two months this combination is strongly followed by a continuance of warm weather. Thus a very warm and very dry June is succeeded by a warm July; or if July be of this description, the ensuing August tends to be warm, the probability in either case being 4 to none out of 7. On the other

hand, a very warm and very dry August is prone to be succeeded by a wet September, 4 to none out of 7. In each of these cases the actual probability is four-sevenths, but the value of this fact is much strengthened by there being *no case* of the opposite.

14. *Cold and Wet.*—If July have this character the next month will generally be a cold one, 3 to none out of 5. So, likewise, a very cold and very wet August tends to be followed by a cold September, 3 to none out of 5.

15. With regard to the meteorological seasons, there is only one case in which the combination of extremes of temperature and moisture in one season seems to definitely influence the following one. A very cold and very wet summer is usually succeeded by a cold autumn. The facts in this case, although few in number, give evidence of a remarkably strong probability, being 3 to none out of 4.

In conclusion, I beg to offer these results, so far as they go, with some confidence, obtained as they are from the *purely numerical treatment* of a long course of carefully recorded facts, whilst they are utterly free from any bias derived from theory. Let it be freely acknowledged that they take the rank only of *empirical* laws, which may some day be knit together by cautious induction to form a part of the future science of meteorology.

---

8. *Notes upon the Rotational Period of the Earth and Revolution Period of the Moon deduced from the Nebular Hypothesis of Laplace. By* W. F. Stanley, *F.G.S., F.R.M.S.*

This paper was in part a defence of the nebular hypothesis of Laplace (last note 'Système du Monde') in opposition to a modification of it proposed by Mr. G. H. Darwin ('Phil. Trans.' 1879, p. 536) as regards the present and former velocities of motions of the earth and moon. The author proposed a theory by which the relative velocities of an earth and moon might be deduced from consideration of the early nebulous conditions. Thus where the nebulous system of the earth was contracting by loss of heat, and the tangential velocity of the exterior parts of it exceeded the centralising action of gravitation, so that it was possible for a satellite system to become detached, there must necessarily be a plane of equilibrium of the particles surrounding the earth where they would be equally solicited by the earth and by its satellite, and this would be the plane of separation of the system. After the separation, the tangential velocities of the separate parts would give the final velocity of the central mass when these parts had condensed to form it. Thus taking the earth and the moon, or their original nebular systems by the simple formula $e : m :: d^2 : d_1^2$, where e and m are earth and moon, and d and d_1 the respective masses. The attraction being directly proportional to the mass, and inversely as the square of the distance, we find by this formula in taking the separate densities and distances of the earth and moon, that the earth at its point of separation where a particle would be in equilibrium would form at first a nebulous globe of 212,347 miles radius. The tangential velocity of the equatorial surface of this globe, assuming it moved at the present rate of the moon, of one revolution in about $27\frac{1}{3}$ of our days, would be a sidereal tangential velocity of 1,334,213 miles in this period. The present velocity of the earth's equator taken for the same period is 679,305 miles, or only about half this. If we assume the *density* of matter of the nebulous system which formed the earth diminished directly as the square of the distance from the centre, then upon condensation the equatorial surface of the present globe should have the final velocity of its original nebulous equator immediately after its separation from the moon, supposing the system acting entirely without friction. But during the formation of the present globe, the matter condensed upon the central mass impressing its momentum of higher tangential velocity upon this mass would cause the centre of the system to have higher radial velocity than the exterior parts, and as the exterior of the system would still be nebulous matter offering considerable resistance to the central mass moving at higher radial velocity, this motion would be necessarily frictional, causing a relative loss of velocity in the central mass which would be developed into heat. It is also

probable that a liquid nucleus was already formed at the period of separation of the earth and moon systems, so that the tangential motion of the exterior nebulous mass surrounding it must be taken into the relative inertia of the denser centre. Therefore the present velocity of the earth's rotation becomes quite rational, allowing this deduction from its former nebular velocity, assuming this has remained a constant on the conditions proposed, according to the hypothesis of Laplace.

9. *On a Galvanic Battery.* *By* C. J. BURNETT.

MONDAY, SEPTEMBER 14.

The following Reports and Papers were read:—

1. *Report of the Committee on Standards of White Light.*

See Reports, p. 61.

2. *Photometry with the Pentane Standard.* *By* A. VERNON HARCOURT, *M.A., F.R.S.*

At Southport two years ago the author exhibited and described a lamp fed with a mixture of gaseous pentane and air which gave constantly when its flame was maintained at a height of $2\frac{1}{2}$ inches (63·5 m.m.) the light of an average sperm candle. Various improvements in the lamp have been made since that date. The narrow tube whose diameter determines the quality of the gas burnt forms the through-way of the plug of a stopcock at the bottom of the siphon, and thus its freedom from obstruction can be verified at any moment. A metal cylinder containing an arrangement of rack and pinion by which the wire above the flame can be adjusted to any desired height has been placed round the burner, and upon this when the flame is exposed to draughts stands a glass chimney partially closed above and below by a perforated metal plate. Thus protected, the flame of the lamp is much steadier than the flame of the candle.

The loss of light due to a thin cylindrical chimney of clear glass has been found by placing such chimneys round a small glow lamp, through which a constant current was passed. It amounts to about 1 per cent. A greater absorption of light, amounting to 6 per cent., occurred with an equally clear chimney of thicker glass. By adjustment of the size and number of the holes in the plates below and above the chimney, the height and brightness of the flame can be made the same when the chimney is used and when it is not.

The relation between the height of the flame of pentane gas burning from a gas-holder and the light emitted has been determined. From a height of 71·5 m.m., at which the flame gives the light of 1·2 candle, down to a height of 35·5 m.m., at which the light is that of 0·3 candle, every millimetre of height corresponds to a light of ·025 or $\frac{1}{40}$ of a candle. Measurements of the light of gas and oil flames ranging from 900 to 2,500 candles were made at a distance of 50 feet in the photometric gallery at the S. Foreland, the pentane burner being fixed at a distance of one or $\sqrt{2}$ foot from the illuminated paper, by adjusting the height of the flame till equal illumination was obtained, bringing down the platinum wire till it touched the tip of the flame, lowering or extinguishing the flame, and reading on a scale of millimetres the height of the wire above the burner.

For testing lighthouse burners with a Bunsen photometer the pentane lamp was used either at its normal height of 63·5 m.m. or, when distant lights had to be measured, with a shorter flame. The relation between the height of flame and light of the lamp has been determined for a range of 30 m.m.

Lastly, the effect of variations of atmospheric pressure upon the pentane flame

has been determined. To give constant light the height of the flame must be increased or diminished by ·2 m.m. for every ·1 inch of barometric height below or above 30 inches. The height of the flame is thus inversely proportional to the atmospheric pressure, as though the flame were a visible cone of gas of constant base. It is found that the height of the flame varies directly with the volume of gas passing to the burner. Recent observations on Ben Nevis show a less rate of variation for a difference of 4 inches of the barometer.

3. *On a Photometer made with Translucent Prisms. By* J. Joly, *B.E.*

When two pieces of a translucent substance such as paraffin are placed in contact along a plane face and illuminated by sources of light placed on opposite sides of this plane and viewed in this plane, they do not appear equally bright unless the illumination by each source is equal. This may be used as a very sensitive test of equality of illumination, and so as a photometer. It has this advantage over both shadow and Bunsen's photometers, that the illuminated surfaces to be compared are in absolute contact along the line of contact of the two pieces of paraffin.

11. *On the Meteorology of Ben Nevis. By* Alexander Buchan.

The advantages possessed by Ben Nevis as a first-class meteorological observatory are these: it is the highest mountain in the British Islands, rising to 4,406 feet; its summit is in horizontal distance little more than four miles from a sea level station at Fort William, and it is situated in the track of Atlantic storms which exercise so preponderating an influence on the weather of Europe, especially in autumn and winter. Its advantages are thus unique, and observations made there are of the highest interest and value in meteorology.

In establishing this national observatory, the object sought to be attained was a knowledge of atmospheric changes and disturbances such as would lead to a juster conception of the great movements of the atmosphere, and of the weather preceding, accompanying, and following these movements. From the knowledge thus gained, and from the Ben Nevis daily observations themselves, the value of forecasts of the weather of the British Islands will, it is believed, be much enhanced.

The importance attached to the Ben Nevis Observatory as contributing aid in framing weather forecasts for the British Islands was soon apparent in discussing the observations in some of their relations to the weather changes of North-Western Europe. The occurrence of remarkable differences from the normals was disclosed in the vertical distribution of the temperature, pressure, and humidity of the atmosphere between the top of Ben Nevis and the sea level at Fort William. As the discussion proceeded it became more and more apparent that these differences gradually grouped themselves into separate classes according to the different types of weather which either prevailed at the time or occurred soon after.

A series of large inquiries thus open up which will lead to important scientific and practical results. These inquiries are, it is unnecessary to say, among the most difficult in physics, and for their satisfactory investigation the directors have thought it essential in the first place to investigate as completely as possible the meteorology of the top of the mountain and of Fort William at its base. This being done, the bearing of the Ben Nevis observations on the weather of the British Islands can be more satisfactorily investigated, particularly the bearing of the observations on the coming weather—an investigation now being prosecuted.

With regard to the climatology of Ben Nevis, reference is made to the Report submitted to this Meeting (see page 90), and to the previous Reports. A large number of other observations have been made and entered in '*the log*' of the observatory which yet remain undiscussed. These embrace optical observations, the state of the sky, and other eye-observations, which cannot be conveniently entered in the daily weather sheet, but which are of the greatest importance in the meteorology of Ben Nevis, particularly in investigating weather changes.

The greatest interest attaches to departures from the normals occurring so repeatedly, of which the thermometric and hygrometric are the most striking. Thus the state of complete saturation of the atmosphere which may be regarded as the characteristic of the weather of the Ben frequently gives way, often quite suddenly, and the air becomes dry, frequently intensely dry, the sky singularly clear, and the temperature rises rapidly, resulting in the relative humidity often falling to 30, or on rarer occasions below 20.

These recurring periods of intense dryness and heat do not occur at any of the stations of the Scottish Meteorological Society at lower levels; and from Mr. Wragge's observations made in 1882 at the eight stations established that year on the slopes of Ben Nevis from sea level to the top, it was shown that the weather conditions of this type are confined to the highest part of the mountains. Heavy rains appear always to accompany this weather, occurring in some neighbouring region. These are the essential characteristics of the foehn; and its frequent occurrence on Ben Nevis which stands isolated above all the hills around it, leads to the conclusion that it is also of not infrequent occurrence in all parts of Europe, at heights in the atmosphere of about 4,400 feet and upwards.

If this be so, consequences of the greatest importance follow. Instances have occurred when the temperature on Ben Nevis has been from 5° to 8° higher than in the vicinity near sea level, and as the normal temperature of Ben Nevis is 16°·3 lower than at Fort William, it follows that the temperature sometimes rises fully 20° above the normal difference. Now as regards the aerial stratum from sea level to 4,406 feet high, this manner of distribution of temperature with height will not be productive of any violent movements. But it is quite otherwise for heights greater than Ben Nevis, where it is evident temperature will fall with height at a rate very greatly exceeding the normal. It is probable that it is from the conditions of unstable equilibrium here indicated that whirlwinds and the more dangerous gusts which occur during storms have their origin.

A comparison of the winds on the top of Ben Nevis with the surface winds shows that sometimes both are within the same cyclonic system or of the same anticyclonic system overspreading that part of Europe at the time. In such cases the direction is nearly always different, and so far as the investigation has been carried it appears that the observed differences give an indication as to whether the coming storm will pass to the north or to the south of Ben Nevis.

Sometimes, however, while the surface winds are part of a cyclone, the winds on Ben Nevis are part of an anticyclone, and *vice versâ*; or putting it in other words, the manner of the distribution of atmospheric pressure at sea level over this region of North-Western Europe is quite different from what obtains over the same region at the height of 4,406 feet. It is this peculiarity in the winds and atmospheric pressure of Ben Nevis, due to its height and proximity to the central paths of the Atlantic storms, which will give to the observations an additional value in framing daily weather forecasts for the British Islands.

---

12. *On some Results of Observations with kitewire-suspended Anemometers up to* 1,300 *feet above ground, or* 1,800 *feet above sea-level, in* 1883–85. *By* E. DOUGLAS ARCHIBALD.

The author began by relating that he had, since the Montreal meeting of the Association, made twenty-five fresh observations, and as these embraced records at altitudes reaching to 1,300 feet above the ground, or 1,800 feet above the sea, he hoped the results from them, as well as fifteen of the former observations combined, might be considered sufficiently numerous and valuable to merit a short discussion.

In the discussion the observations were divided into six groups, according to altitude, and the exponent for each observation in the formula $\frac{V}{v} = \left(\frac{H}{h}\right)^x$ being calculated, the means were taken for each group, with the following results:

TABLE I.

Group	Mean height of upper instrument above ground	Mean height of lower instrument above ground	Mean velocity of upper instrument	Mean velocity of lower instrument	Mean of both	Mean value of x
	H	h	V	v		
(1)	250	102	1,617	1,174	1,395	·372
(2)	322	128	2,232	1,679	1,955	·307
(3)	407	179	1,705	1,385	1,545	·275
(4)	549	252	2,107	1,773	1,940	·237
(5)	795	481	2,192	1,957	2,074	·250
(6)	1,095	767	2,236	2,096	2,166	·194

From which it is manifest (as well as from the individual observations) that *while the velocity always increases with the height above the ground as far as* 1,800 *feet above sea-level, the ratio of the increase measured by the exponent x progressively diminishes.*[1]

As the station itself is 500 feet above sea-level, the motion of the air at some height above the surface should correspond more or less with that at an equivalent height above the sea over an open sea-level plain. Where this actually is exactly the case is difficult to determine, but assuming that it is approximately the case at the mean level of group 6, or 931 feet above the ground, and adding 400 feet to both heights, we get $x = 0{\cdot}26$, which is nearly identical with the value already

[1] The exceptional case of group 5 being due to the inclusion in that group of an abnormally large value of x corresponding to an equally abnormally small velocity.

determined by the author as the value of the exponent in the formula $\frac{V}{v} = \left(\frac{H}{h}\right)^x$ which best accords with the results of Dr. Vettin's cloud observations over Berlin extending from 1,600 to 25,000 feet above sea-level ('Nature,' vol. xxv. p. 506), and the result shows not only that the observations of the author agree generally with those of Dr. Vettin, but also that beyond a certain height the exponent becomes nearly constant. The author finds, apart from height, that the values of the exponent, or in other words the ratio of the increase of the velocity with the height, is affected principally by four factors: (1) the mean velocity of the two heights; (2) the hour of the day; (3) the direction of the wind; and (4) the time of year.

On comparing the exponents for each group with each of these factors in turn variations appear of a periodic character, which in some cases are difficult to exhibit independently, owing to chance arrangements of the other factors affecting the results co-directionally. In the first two cases, however, the results can be shown to be independent of the other factors, and lead to the enunciation of the following laws:—

1. Above the first 160 feet from the ground, the exponent generally decreases with an increase of velocity, and *vice versâ*. Below the first 160 feet this law is apparently reversed, owing probably to undue sheltering of the lower instrument by surrounding objects.

2. When the exponents are arranged for different hours of the day, for heights above 160 feet and up to 1,300 feet above the ground, the exponents in all the four upper groups show a uniform increase from a minimum value about 2 or 3 P.M. to a maximum about 7 or 8 P.M. Below 160 feet the first two groups show some signs of a contrary variation, which may admit of an explanation similar to that for the preceding law.

This second law is in complete agreement with Dr. Köpvpen's theory of the diurnal period in the velocity of wind and other casual observations of the author, but requires more morning observations to confirm it.

The other laws of which indications have been observed are a maximum value of the exponent for winds from a westerly quarter and a minimum for those from an easterly quarter. Also a maximum value of x in October falling to a minimum in the winter and rising again to a maximum in spring and early summer, but these are more involved by the co-existence of the other factors.

The last law, if found to be confirmed, might be due in part to the changes in terrestrial friction due to the falling of the leaf in winter.

---

13. *On the Measurement of the Movements of the Ground, with reference to proposed Earthquake Observations on Ben Nevis. By* Professor J. A. Ewing, *B.Sc., F.R.S.E.*

Measurements of earth movements are of two distinct types. In one type the thing measured is the displacement, or one or more components of the displacement, of a point on the earth's surface. For this purpose the mechanical problem is to obtain a steady point to be used as an origin of reference, and this is effected by making use of the resistance which a mass opposes to any change of motion. This may be called the *inertia method* of observing earth movements. It is applicable to ordinary earthquakes, and also to the more minute earth tremors, which would pass unnoticed if instrumental means of detecting their presence were not employed. The steady point is to be obtained by suspending a heavy mass (with one, two, or three degrees of freedom) in such a manner that its equilibrium is very nearly neutral. Any moderately sudden displacement of the ground in the direction in which the mass has freedom to move leaves the mass almost undisturbed, and the displacement of the ground is therefore easily measured or recorded by a suitable autographic arrangement, which must be so designed as to introduce exceedingly little friction.

The second type of measurements is that in which the thing measured is any

change in the inclination of the surface of the ground relatively to the vertical. Movements of this class have been examined by d'Abbadie and Plantamour, and also by G. H. and H. Darwin, who have given the results of their observations to the British Association in two Reports on the Lunar Disturbance of Gravity (1882-3). Perhaps the most convenient name for these movements is earth-tiltings. They are measured by what may be called the *equilibrium method.* A pendulum suspended in a viscous fluid is employed to show by its equilibrium position the true direction of the vertical, and that is compared with the direction of a line which is fixed relatively to the surface of the ground; or, instead of a pendulum, a dish of mercury or a pair of spirit-levels are employed to define a truly horizontal surface, and the tilting of the earth's surface relatively to that is observed.

This method is practicable only when the displacements of the surface have so great a vertical amplitude in comparison with their horizontal wave-length that the slope of the wave is sensible; and further, only when the changes of slope occur slowly enough to put the inertia of the pendulum or fluid out of account. On the other hand, the inertia method is applicable only when the displacements have so short a period in comparison with their amplitude that the acceleration of the ground during the greater part of the motion is large relatively to the frictional resistance of the suspended mass. Between ordinary earthquakes and tremors on the one hand, capable of observation by the inertia method, and slow earth-tiltings on the other, capable of observation by the equilibrium method, it is at least possible that there may lie many movements not reducible to either type. For example, if successive upheaval and subsidence of small amplitude were to occur with a very long horizontal wave-length, and with a period of say one or two minutes or more, it would be practically impossible even to detect its existence by either of the methods named, unless by chance it were repeated several times with uniform period in the presence of a very frictionless vibrator whose free period happened to agree nearly with the period of the disturbance; even then no measurement of its amount could be made. We are in fact forced to classify earth-movements under the two heads which have been named—not because there is any necessary discontinuity between the two, but because they must be treated by two entirely distinct modes of observation.

For the measurement of palpable earthquakes by the inertia method the writer has devised many instruments which have been successfully applied to the registration of Japanese earthquakes, and which are described in a memoir on earthquake measurement published in 1883 by the University of Tokio. He has not attempted in any case to give the astatically suspended mass three degrees of freedom, and nothing would be gained by doing so. An instrument with two degrees of freedom is now exhibited to the Association. It consists of an ordinary pendulum coupled with an inverted pendulum in such a manner that the two bobs move together in any horizontal direction. This combination of a stable with an unstable mass can be adjusted to give any desired degree of astaticism. In practice it is convenient to allow the joint mass to have a free period of from five to ten seconds—the period of ordinary earthquake waves being much less than this. A long and light lever pivoted to the frame of the instrument at one point and to the steady mass at another forms a registering index, by which a magnified trace of the earth's horizontal movement is deposited on a fixed plate of smoked glass with the least possible friction.

In another instrument two separate components of horizontal motion are determined each by a horizontal pendulum tilted slightly forwards to give a small degree of stability, and furnished with a multiplying pointer. In this instrument the pointers trace the successive movements of the earth on a plate of smoked glass, which is kept revolving uniformly by clockwork. The velocity and acceleration of the movements are deducible from the records. This is the standard form of seismograph employed by the writer; and to make the information it gives complete, another instrument for registering on the same plate the vertical motion of the ground is added.

The vertical motion seismograph is a horizontal lever, supported on a horizontal fixed axis, and carrying at one end a heavy mass. A spring, attached to a fixed

point above, holds up the lever by pulling on a point near the fulcrum. To make the mass nearly astatic the point at which the spring's pull is applied is situated below the horizontal line of the lever, so that when the spring, by (say) being lengthened, pulls with more force, the point of application moves nearer the fulcrum, and the moment of the pull remains very nearly equal to the moment of the weight.

Apart from the registration of palpable earthquakes, the inertia method is to be applied to the minute earth tremors which have been observed in Italy by Bertelli and Rossi, and which are probably to be found wherever and whenever one searches for them with sufficient care. But in dealing with them no mechanical means of recording can well be applied on account of its friction, and a still more frictionless method of suspending the heavy mass is desirable. The writer prefers for this purpose a mode of astatic suspension (of which a model was exhibited) based on Tchebicheff's straight line motion; and to detect the movement of the ground he observes, by a microscope fixed rigidly to the frame of the machine, the displacement of the frame with respect to the suspended mass. This is Bertelli's method, except for the substitution of a nearly astatic mass for the stable mass used by him—namely, the bob of a short pendulum—which, of course, gives a misleading magnification of certain vibrations.

The writer was recently requested by the directors of the Ben Nevis Observatory to design seismometers for use there, and obtained a Government grant for their construction. The equipment at Ben Nevis will include recording seismographs and a micro-seismometer of the kind just described. To measure slow earth-tiltings an instrument is being constructed in which a modification (due to Wolf) of d'Abbadie's arrangement (described in Professor Darwin's Reports) is followed. Light from a lamp travels some twenty feet horizontally to a mirror inclined at 45 degrees to the horizon. It passes vertically down through a lens which brings the rays into parallelism. They strike two reflecting surfaces—one the surface of a basin of mercury, the other a plane mirror very rigidly fixed to the rock. The rays come back to form two images near the source, and any relative displacement of the two images is measured by a micrometer microscope. In the choice and design of this instrument the writer has to acknowledge much assistance from Professor G. H. Darwin. This apparatus, like the others, was intended for Ben Nevis, but a visit to the observatory there has convinced the writer that to use it on that site, and in the atmosphere which prevails on the top, would be a matter of extreme difficulty, and that, in the first instance at least, observations should be made with it on lower ground.

---

14. *On the supposed Change of Climate in the British Isles within recent years. By* THOMAS HEATH, *B.A.*

This note gives the result of an examination of the Meteorological Tables published by the Registrar-General of Births, Marriages, &c., in Scotland, and shows that there has been no material alteration in the mean temperature, either of all Scotland or of six stations whose records have been separately examined; but that there has been a decided increase in the amount of rainfall within recent years, which increase seems to exhibit itself more particularly on the eastern coast.

---

15. *On Malvern, Queen of Inland Health Resorts, and on improved Hygrometric Observations. By* Professor C. PIAZZI SMYTH, *F.R.S.E.*

The conditions for health resorts so often include useful requirements for scientific observing stations, that the author hoped the identification, chiefly by hygrometrical observations, of a remarkably favourable example of the former, might be interesting to a British Association meeting.

Having first carried on several weeks' observing in a low level region of the Midland Counties, he then removed to Malvern Hills with the same instruments, and immediately obtained more than twice the amount of depression of the wet below the dry bulb thermometer, as ordinarily observed at the first station.

The reasons for this remarkable dryness he then discusses, and adds to what has been already advanced by local medical men, the elevation of Malvern above the *stratus*—fog level of the low country, the effect of rising above which he compares, though on a far smaller scale, to rising above the north-east wind's cloud level on the Peak of Teneriffe.

Several other circumstances are then detailed, which all tend to enhance the mean temperature, check the variations or range of temperature, and decrease the strength of the winds at Malvern, combining altogether to produce the most genial and healthy atmosphere yet ascertained in Great Britain.

---

16. *The Annual Rainfall of the British Islands.* *By* ALEXANDER BUCHAN.

As regards the British Islands, the greatest differences in local climates arise from differences in the rainfall. If the climate of Skye be compared with that of the coasts of the Moray Firth, in no month will the mean temperatures be found to differ so much as $2^{\circ}\cdot 0$, and for several months of the year they are nearly identical. But the annual rainfall of Skye rises to, and in many places exceeds 100 inches; whereas from the mouth of the Spey to Tain, the rainfall is little more than a fourth part of that amount; and this difference in the rainfall, with the clear skies and strong sunshine which accompany it, renders the southern shores of the Moray Firth one of the earliest and finest grain-producing districts of Scotland, whereas Skye is one of the latest and poorest grain-producing districts. Hence the paramount importance of the rainfall in the climatology of a country.

The temperatures of comparatively few places are required, in order to draw, with approximate correctness, the lines of mean atmospheric pressure and temperature for any particular region. But with the rainfall it is very different, this being, of meteorological data, the most difficult to represent cartographically, and there is no other way to arrive at a tolerable approximation to the average rainfall of a district than by numerous rain-observing stations. This inquiry, the results of which are represented on the map exhibited, is based on observations of the rainfall made at 1,080 stations in England and Wales, 547 in Scotland, and 213 in Ireland—in all 1,840; and while it cannot be said that any district is overstocked with rain-gauges, large districts remain wholly, or at least very imperfectly, represented.

The period which has been selected for this inquiry is the twenty-four years extending from 1860 to 1883, it being only in 1860 that fairly adequate data for the whole of the British Islands began to be available by the appearance of Symons' 'British Rainfall.' In Mr. Symons' energetic hands, aided for some years by grants from the British Association, the stations for observation of the rainfall, and the publication, have increased year by year, till in 1884 the stations number nearly 2,600, and the publication occupies 242 pages. While the returns published by the Meteorological Societies of England and Scotland, and returns from other sources have been utilised, it is mainly on Mr. Symons' invaluable annuals that this inquiry is based.

The methods of discussion employed, and the average annual rainfall of the different stations, are detailed at length in the 'Journal of the Scottish Meteorological Society,' recently published.

The distribution of the rainfall for the twenty-four years over the British Islands is shown by six shadings indicating the districts where the annual rainfall does not exceed 25 inches; is from 25 to 30 inches; from 30 to 40 inches; from 40 to 60 inches; from 60 to 80 inches; and lastly above 80 inches.

The regions of heaviest rainfall, marked off by an average of 80 inches or upwards annually, are four—Skye and a large portion of the mainland to the south-east as far as Luss on Loch Lomond; the greater part of the Lake district; a long strip including the more mountainous part of North Wales; and the mountainous district in the south-east of Wales.

The West Highlands present the most extensive region of heaviest rainfall in the British Islands. The mountain masses along whose slopes the rainfall is pre-

cipitated offer a practically unbroken face of highlands to the rain-bringing winds of the Atlantic. Further, these mountain masses present innumerabls lochs and valleys directly in the course of these winds, up which therefore the winds are borne, and being cooled as they ascend, pour down those deluges of rain which deeply trench the sides of the mountains in the lines of their watercourses. The heaviest rainfall in Scotland, 128·50 inches, is at Glencroe in this district.

On the other hand, the smallest rainfall, varying from about 22·50 inches to 25·00 inches, overspreads a large portion of the south-east of England, extending from the Humber to the estuary of the Thames, exclusive of the higher grouuds of Lincoln and Norfolk, where the rainfall rises above 25 inches. To this is to be added a small patch in the valley of the Thames, from Kew to Marlow. In every other part of the British Islands the rainfall exceeds 25 inches.

The districts characterised by rainfalls intermediate between these extremes were then referred to, and it was pointed out that everywhere the key to the distribution of the rainfall is the direction of the rain-bringing winds in their relation to the physical configuration of the surface. Of this law or method of the distribution, the rainfall over the south-western counties of England is one of the best examples. Some of the other more striking illustrations are the Bristol Channel, which secures an increased rainfall for a large portion of central England; the Solway Firth, together with the mountainous regions on each side of the entrance to it, in their influence on the singular distribution of the rainfall of the south of Scotland and north of England adjoining; and the mountains of North Wales, with the estuary of the Dee, in their relations to the rainfall of a large portion of England lying to the east and north-east.

As regards the rainfall of the twenty-four years from 1860 to 1883, the most noteworthy feature is the comparatively large average amount for the second half of the period over nearly the whole of the British Islands. The excess is most marked over the more strictly eastern districts, the means of the 12 years ending 1883 being generally from 5 to 10 per cent. greater than the means for the twenty-four years.

---

17. *Remarkable Occurrence during the Thunderstorm of August* 6, 1885 *at Albrighton. By* J. Bedford Elwell.

St. Cuthbert's, my residence, is situated at Albrighton, ten miles from Wolverhampton, with which it is connected by telephone. The house has a lightning protector twenty-five years old. The telephone wire very improperly makes earth on this conductor.

The storm was at its height about half-past eight in the evening, and we had just retired to the drawing-room, there being only a single lamp left alight in the dining-room, in the centre of the corona. The telephone-bell was sounding with every flash of lightning, when suddenly a report like a rifle shot was heard in the hall, and at the same instant the servants in the dining-room were plunged into darkness by the lamp in the corona flashing up and then going out. (Another lamp was immediately put in, showing the leads were not injured.) Also at the same moment the telephone wires were both fused. The wire sometimes used to connect the telephone with the drawing-room was also fused, and through it the lightning tried to make earth (or *vice versâ*) all over the electric light system, succeeding in one place, in a bedroom over the entrance hall, where a bell-pull was close to one of the leads. The current struck across—showing an E.M.F. of many thousand volts—and fused the bell wire. None of the lead cut-outs were fused on any of the wires.

On examining the burnt lamp in the dining-room, it was found to be so blackened that (although it was perfectly clear and bright the moment before, and, being a 48 volt Swan lamp, could not be overrun from 24 cells) it was with difficulty that the filament could be seen. It was burnt off at *both ends* where the platinum wire joined, *and lay entire* in the bottom of the globe. A few globules of melted glass or platinum were also rolling about within the globe.

The glass globe has become a beautiful mirror by the fine particles of platinum that have been projected against it.

N.B.—A *separate earth-plate* has since been put to the telephone, so that nothing of the kind can again happen.

---

18. *On a supposed Periodicity of the Cyclones of the Indian Ocean south of the Equator. By* CHARLES MELDRUM, *F.R.S.*

In papers printed in the Reports for 1872, 1873, 1874, and 1876, I endeavoured to show that there were grounds for supposing that the cyclones of the Indian Ocean south of the equator increased in number, extent, and intensity from a minimum in one year to a maximum in another, and then decreased to a minimum, the period or cycle apparently corresponding with the eleven-year period of solar activity.

From the data given in the last of those papers (Report for 1876, page 267) it would appear that from 1856 to 1875, the years of minimum cyclone-activity were 1856 and 1867, and the years of maximum activity 1861 and 1872, but that the results for each of those years did not differ much from the results for the year immediately preceding or following it, the variation near the turning-points being small.

Before giving a brief outline of the results which have been obtained since 1875, it may be well to mention that the sources of information were the same as in former years. Two clerks were constantly occupied in tabulating the meteorological observations contained in the log-books of vessels that arrived in the harbour of Port Louis from different places. The number of days' observations tabulated in each year, that is, observations extending over twenty-four hours, and made in different parts of the Ocean, was as follows:—

Years	Days' Observations	Years	Days' Observations
1876	17,017	1881	16,473
1877	17,005	1882	15,089
1878	17,050	1883	16,930
1879	15,889	1884	15,697
1880	17,306		

The tables give an average of forty-six observations of twenty-four hours each for every day of the nine years over the frequented parts of the Ocean.

All details and reports respecting hurricanes, storms, or gales, were recorded in separate registers.

For each day on which there was a gale in any part of the Ocean between the equator and the parallel of 34° S. a chart was prepared, showing as nearly as possible the positions of the vessels, the direction and force of the wind &c. at a certain hour, viz., noon on the meridian of 60° E.

From these synoptic charts, the details given from hour to hour in the log-books, and all the information obtained from other sources, the positions of the centres of cyclones at noon on each day were determined, and the tracks laid down on separate charts.

Nine Cyclone-Track Charts have thus been prepared, since 1875, namely, one for each of the years 1876–84.

These Track-Charts, together with the twenty that had previously been prepared for the years 1856–75 show, as far as has yet been ascertained, the tracks of the cyclones of the Indian Ocean south of the equator in each of the years 1856–84, and the tracks for the years 1848–55 are nearly ready.

With respect to the period 1876–84, the *areas* of the cyclones and the *distances* traversed have not yet been determined, but upon the whole the *number* and *duration* of the cyclones decreased to a minimum in 1880, and then increased till, in 1884, they were more than double of what they were in 1880.

From the accompanying Track-Charts for the eleven years 1856, 1857, 1860, 1861, 1867, 1868, 1871, 1872, 1879, 1880, and 1884, it will be seen that the number

and duration of the cyclones of 1856 and 1857 were much less than those of the cyclones of 1860 and 1861: that the number and duration of the cyclones of 1867 and 1868 were much less than those of 1860 and 1861 on the one hand, and also than those of 1871 and 1872 on the other; and that the number and duration of the cyclones of 1879 and 1880 were much less than those of the cyclones of 1871, 1872, and 1884.

It would appear, however, that in 1884 there was less cyclone-activity than in 1861 and 1872.

---

19. *A new Wind Vane or Anemoscope, specially designed for the use of Meteorologists.* *By* G. M. WHIPPLE, *B.Sc., F.R.A.S.*

The author described a modification of the ordinary wind vane which serves to render its indications more certain when read from a distance.

He permanently attaches the letters N.E.S.W. to the vane and carries them round with it. A fixed pointer is suitably placed beside the vane or beneath it, and the observer merely looks at the letters and determines the direction of the wind from their position with reference to the pointer.[1]

---

20. *On the Third Magnetic Survey of Scotland.* *By* Professor T. E. THORPE, *F.R.S., and* A. W. RÜCKER, *F.R.S.*

At the last meeting of the British Association held in Aberdeen, Professor Balfour Stewart presented the Report of the Observations made in connection with the Magnetic Survey of Scotland in the years 1857 and 1858. This Survey was undertaken at the request of the Association by the late Mr. Welsh, of the Kew Observatory, and the report is published in the account of the Society's Proceedings for 1859. Mr. Welsh's observations constitute the second magnetic survey of Scotland, the results of the first survey having been recorded by the late Sir Edward Sabine in the 'Report of the British Association for 1838.'

In a 'Note on the Irregularities in Magnetic Inclination on the West Coast of Scotland,' published in the Proceedings of the Royal Society for Nov. 15, 1883, we drew attention to the fact that the present time was very opportune for a new magnetic survey of Scotland as part of a general survey of the British Islands. 'More than twenty-five years,' it was remarked, 'have elapsed since Mr. Welsh made his survey, and this was separated by an interval of twenty-one years from that which we owe to the joint labours of Sir Edward Sabine, Sir James Ross, and Mr. Fox. The instruments and methods of observation in 1858 were greatly superior to those in 1836–7, and hence a new survey, made during the approaching period of minimum sun-spot disturbance and on stations selected with careful reference to their geological character, would undoubtedly afford far more accurate data as to the absolute value of the magnetic elements, and as to the extent of secular change in this part of the world, than we at present possess.'

As the accounts of the previous surveys were published in the Reports of the British Association, we may perhaps be allowed to take this opportunity of intimating to the members that we have during this and the preceding summer made the necessary observations for the survey suggested in the above remarks. A determination of the magnetic elements, that is of inclination, declination, and force, has been made at fifty stations. The great increase in the facilities for travelling in Scotland since 1857–8 has placed us at a considerable advantage as compared with Mr. Welsh for reaching various places at which observations were desirable. The greater number of the coast stations were visited in a yacht belonging to one of us; in this way we were able to observe under more favourable conditions as to choice of situation and duration of stay, than if we had been dependent upon the ordinary steamboat service.

The following is a list of the stations:—

[1] For illustration, see *Quart. Jl. Roy. Met. Soc.* vol. xi. p. 64.

Berwick-on-Tweed (W.).	Crianlarich.	Soa.
Hawick.	Oban (W.).	Canna.
Dumfries (W.).	Kerrara.	Loch Boisdale.
Stranraer (W.).	Iona.	Loch Maddy.
Ayr (W.).	Coll.	Stornoway (W.).
Carstairs (W.).	Tiree.	Callernish (W.).
Edinburgh (W.).	Loch Aylort.	Gairloch.
Glasgow (W.).	Bannavie (W.).	Loch Inver (W.).
Fairlie.	Dalwhinnie (W.).	Loch Eriboll.
Campbelltown (W.).	Ballater.	Thurso (W.).
Port Askeg (Islay) (W.).	Aberdeen (W.).	Wick (W.).
Tarbert (Loch Fyne).	Banff (W.).	Golspie (W.).
Strachur.	Elgin (W.).	Lairg.
Stirling.	Boat of Garten.	Stromness (W.).
Dundee.	Inverness (W.).	Kirkwall (W.).
Pitlochrie (W.).	Fort Augustus (W.).	Lerwick (W.).
Crieff.	Kyle Akin (W.).	

W. signifies a station also observed at by Mr. Welsh in 1857 or 1858. The stations are distributed as uniformly as possible over the whole area of Scotland, and they have been chosen with the view of repeating the measurements at as many as possible of the positions selected by Mr. Welsh, and, at the same time, of avoiding as far as might be regions of great local disturbance. At stations where Mr. Welsh's notes gave the requisite details we have observed when possible on the exact site he occupied. At new stations we have been careful to select positions which are likely to remain open, so that future observations can be made there.

Some of the declinations determined by Mr. Welsh on the west coast were discarded when his results were published by Professor Stewart, as the mirror of the magnetometer was found to have been out of adjustment on several occasions. Owing to the improvements made in the Kew Unifilar since the time of the last survey, the liability to error from this source is practically obviated: it is now possible to ascertain readily whether the mirror is properly set and, if necessary, to readjust it, before making the solar azimuth observations. With the view, however, of still further minimising the errors due to the axis of the mirror being either not parallel to its plane, or not perpendicular to the line of collimation of the telescope, our observations of the transits have been made by alternate reversals of the axles in its bearing and by back and front observations of the sun.

The accuracy of the determinations of solar azimuth, and hence of the declination, has been greatly increased by the circumstance that we were able to make frequent comparisons of our chronometers with the time signals sent daily from Greenwich at 10 A.M. and 1 P.M. along the telegraphic system of England and Scotland. We have to thank Mr. Cunynghame, the Director-General of Telegraphs at Edinburgh, and Messrs. Tansley and Redford, Superintendents of the Glasgow and Ayr districts respectively, for the facilities afforded us in this part of our work. We are also much indebted to the postmasters at the various places visited for the readiness with which they arranged for the transmission or reception of the signals.

Our Magnetometer (No. 60 Elliott) and Dip Circle (No. 74 Dover) were compared with the Kew instruments by observations taken by ourselves and by Mr. T. W. Baker at the Kew Observatory. Our thanks are due to the Kew Committee of the Royal Society and to Mr. G. W. Whipple for the assistance thus rendered.

The actual work of the survey was prefaced by an inquiry as to the nature and extent of the influence exerted by the great centres of local disturbance at various parts along the west coast of Scotland. With a view of obtaining information on this matter we selected the island of Mull, the geological characters of which have been very fully described by Professor Judd, and which, as Mr. Welsh's determinations show, exerts a highly disturbing influence. The observations were made in the summer of 1883, and are published in the 'Proceedings of the Royal Society' for 1883–4. They serve to indicate within what limits such centres of local disturbance may be approached without affecting the general direction of the

isoclinals. The survey was begun in the summer of 1884, and was continued during the spring, summer, and autumn of the present year. We have been assisted in some of our later observations by Mr. A. P. Laurie, of King's College, Cambridge, who was good enough to undertake the measurement of the dips at a number of the inland stations. Our best thanks are due to Mr. Laurie for the valuable help thus rendered.

It is hardly possible for us as yet to say anything about the general results of the survey, as the observations are only partially reduced. We trust to be able to complete the calculations without delay. We venture, however, to hope that the statement that all the necessary observations for what now constitutes the third Magnetic Survey of Scotland have been taken, may not be without interest for the members of the British Association.

TUESDAY, SEPTEMBER 15.

The following Reports and Papers were read:—

1. *Report of the Committee for considering the best means of Comparing and Reducing Magnetic Observations.*—See Reports, p. 65.

2. *Report of the Committee for considering the best methods of recording the direct Intensity of Solar Radiation.*—See Reports, p. 156.

3. *On a means of obtaining constant known Temperatures. By* Professor W. Ramsay, *Ph.D., and* Sydney Young, *D.Sc.*

This method, which has involved the determination of the true vapour-pressures of numerous substances, with help of mercurial, air, and vapour-pressure thermometers, is published in full in the 'Trans. Chem. Soc.,' Sept., 1885.

4. *On certain facts in Thermodynamics. By* Professor W. Ramsay, *Ph.D., and* Sydney Young, *D.Sc.*

This paper has reference to the equation

$$\frac{L}{s_1 - s_2} = \frac{dp}{dt}\frac{T}{J}$$

While Dr. Ramsay discovered in 1877 that $\frac{L}{s_1 - s_2}$ at the same pressure is approximately constant for all liquids for which there exist data, the correctness of the data and assumptions on which the statement is based was open to question. Hence the investigation was unpublished until a relation in some degree connected with this was rediscovered by Mr. Trouton, 'Phil. Mag.' 1884, p. 54. Since then, Dr. Young noticed that the value of $\frac{dp}{dt}\frac{T}{J}$ at the same pressure is an approximate constant for all liquids, and as the data in this case are much more reliable than in the former, it has been thought desirable to publish both researches under one title.

The first law is:—*The amounts of heat required to produce unit increase of volume in the passage from the liquid to the gaseous state at the boiling-point under normal pressure are approximately constant for all bodies; or* $\frac{L}{s_1 - s_2} = C$.

The second law is:—*If the amounts of heat required to produce unit increase of volume in the passage from the liquid to the gaseous state be compared at different pressures for any two bodies, then the ratio of this amount at the boiling-point under*

a pressure p_1 to the amount at another pressure p_2 is approximately constant for all liquids; *or*

$$\frac{L}{s_1 - s_2} \text{ at } p_1 \text{ bears a constant proportion to—}$$

$$\frac{L}{s_1 - s_2} \text{ at } p_2 \text{ for all liquids and probably for all solids.}$$

It has also been noticed as a corollary from the first law that the internal and total work bear an approximately constant ratio to each other for any one pressure, whatever the liquid.

In considering the second part of the equation, the following relations have been noticed:—

If a curve be constructed to represent the relation of temperature to pressure for any liquid, and if tangents be drawn to touch the curve at various points corresponding to certain temperatures, these tangents will give the rate of increase of pressure per unit rise of temperature, in other words, the value $\frac{dp}{dt}$ for those temperatures.

If we construct curves for a number of substances, and determine the value of $\frac{dp}{dt}$ for each of them at the same temperature, it is clear that the values obtained will differ widely, and will be greater for volatile substances than for those which are less volatile. But if we determine the values of $\frac{dp}{dt}$ not at the same temperature, but at the same pressure, the conditions under which the comparison is made will be more similar, and the resulting values may be expected to differ much less. In the calculation of the vapour pressures of a number of substances for each degree between certain limits of pressure, it became evident that at any given pressure the rate of increase was generally, though not always, greater for the volatile substances than for the less volatile.

A closer study of the matter led to the following generalisations:—

1. The products of the rate of increase of pressure per unit difference of temperature into the absolute temperature $\frac{dp}{dt}.T$ are approximately the same for all stable substances at the same pressure, but the differences are real and are not due to errors of experiment or calculation.

2. The rate of increase of this value $\frac{dp}{dt}.T$ with rise of pressure is the same for all stable bodies, at any rate for pressures between 150 and 2,000 mms., while for alcohol and water it is the same for all pressures between 100 and 20,000 mms.

3. In the case of certain substances nearly related to each other, such as bromo- and chlorobenzene, or ethyl bromide and chloride, the ratio of the absolute temperatures of the related bodies at any given pressure is a constant.

Complete paper to be found in 'Phil. Mag.,' December 1885.

5. *Report on Optical Theories.* *By* R. T. Glazebrook, *M.A., F.R.S.*

See Reports, p. 157.

---

6. *On a Point in the Theory of Double Refraction.* *By* R. T. Glazebrook, *M.A., F.R.S.*

The author suggested that the theory of double refraction given by Lord Rayleigh, in which the ether is supposed to have an effective density different in different directions, might be modified so as to agree with Fresnel's theory if it be not necessary to assume that the ether offers an infinite resistance to compression, but only that as compared with its rigidity, its incompressibility is very great, and

further, that in a crystal the light vibrations are normal to the ray, not to the wave normal, as was pointed out by Boussinesq, and referred to by Ketteler in some of his papers.

7. *Exhibition of a Mechanical Model illustrating some properties of the Ether.* *By* G. F. FITZGERALD, *F.R.S.*

8. *On the Constitution of the Luminiferous Ether on the Vortex Atom Theory.* *By* Professor W. M. HICKS, *M.A., F.R.S.*

The simple incompressible fluid necessary on the vortex atom theory is quite incapable of transmitting vibrations similar to those of light. The author has therefore considered the possibility of transmitting waves through a medium which consists of this fluid modified so as to contain small vortex rings closely packed together. The rings are supposed composed of the same material as the rest of the fluid, to be very small compared with the wave length, and at distances from one another also small compared with the wave length. Their motion of translation is also taken to be so comparatively slow that very many waves can pass over any one before it has much changed its position. Such a medium would probably act as a fluid for larger motions.

The vibration in the wave front may be (1) swinging, such as a ring oscillating on a diameter, (2) transversal vibrations of the ring, (3) vibrations normal to the plane of the rings, (4) apertural vibrations. Of these (3) seems to be impossible. If r be the radius of the rings, l the distances of their planes, μ their cyclic constant, and v the velocity of translation, the author found
for

$$(1)\ v \propto \frac{\mu}{l}\left(\frac{r}{l}\right)^4$$

for

$$(2)\ v \propto \frac{\mu}{l}\left(\frac{r}{l}\right)^2$$

whilst for (4) in case of rings arranged parallel to a wave front,

$$v \propto \frac{\mu r^4 l^2}{(l^2+4r^2)^{\frac{5}{2}}}.$$

9. *On an improved Apparatus for Christiansen's Experiment.*[1] *By* Lord RAYLEIGH, *D.C.L., LL.D., F.R.S.*

10. *Optical Comparison of Methods for observing small Rotations.*[2] *By* Lord RAYLEIGH, *D.C.L., LL.D., F.R.S.*

11. *On the Accuracy of Focus necessary for sensibly perfect Definition.*[3] *By* Lord RAYLEIGH, *D.C.L., LL.D., F.R.S.*

12. *On Electro-Optic Action of a charged Franklin's Plate.*[4] *By* J. KERR, *LL.D.*

The experiments described in this paper were carried out by the author in 1882, and he has now made them known in view of certain statements made by M. Wiedemann in his 'Die Lehre von der Electricität,' vol. ii.; particularly where

[1] Published in the *Phil. Mag.*, Oct. 1885. [2] *Ibid.*
[3] *Ibid.* [4] *Ibid.*

he says that there appears to be no electro-optic double refraction in the case of a uniformly charged Franklin's plate. The results obtained were shown by the author to prove that electrostatically strained glass acts in the polariscope as if compressed along the lines of electric force, *and this always, whether the electric field is uniform or not.*

---

13. *On Magnetic Double Circular Refraction.*[1] *By* DE WITT B. BRACE, *Ph.D.*

The main object of the investigation has been to determine whether the refractive index of a medium under magnetic stress experiences a change for circularly polarised light when the direction of propagation is that of the lines of force.

In connection with the investigation, several important equations have been deduced for the case of reflection and refraction near the critical angle. A very small change in the refractive index produces a very great change in the angle of deviation and in the amount of reflected light. A slight change in the angle of incidence may produce a very great change in the angle of deviation of the reflected or refracted ray.

In the first experiment a piece of Faraday glass was placed in a strong magnetic field, and one of the two interfering rays from a Jamin's interference refractor allowed to pass through it in the direction of the lines of force. When the ray was circularly polarised, a displacement of the bands was observed, the direction of which depended on whether the ray was right or left-handed circularly polarised. This displacement became less and less distinct as the ray was more and more elliptically polarised. Every ray is then broken up into its opposite circular components, and either the velocity of propagation, or the phase (period), or both, changes. The observed displacement was ·1355, while the value calculated from a double rotation of the plane of polarisation of 49° 20′ was ·137.

Several experiments for direct observation were made, which seemed to indicate no change in the velocity of propagation, but a change in the phase. In one of these experiments, a prism of glass was placed between the poles of a magnet, so that the rays were parallel to the lines of force and perpendicular to the first face of the prism, and were refracted out at the second face at a very large angle. Refraction then took place at a surface near the critical angle, and a slight change in the refractive index due to the induced magnetic stress would produce a very large deviation, in accordance with the equations found. The two halves of the narrow image were oppositely circularly polarised, so that each should have been displaced in the opposite direction. There should also have been a slight change in the intensity of the two halves. Nothing of the sort could be observed. Direct measurements of the rotation of the plane of polarisation, and comparison with a Fresnel's double quartz prism, showed that the effect was within the limits of observation if such a change in the refractive index had occurred.

14. *Determination of the Heliographic Latitude and Longitude of Sun-spots. By* Professor A. W. THOMSON.

In the 'Observatory,' published monthly, we have for any day—The Position Angle of the Sun's Axis, and the Heliographic Latitude and Longitude of the Centre of Sun's Disc.

The method devised by me consists in throwing the image of the sun from an equatorial telescope on to a disc representing the sun, with lines of latitude and longitude drawn thereon, and reading off the latitude and longitude of any spot.

The latitude of the centre of sun's disc varies from 0° to about 7°; a cardboard

[1] Inaugural Dissertation, '*Ueber die magnetische Drehung der Polarisationsebene und einige besondere Fälle der Refraction.*' Berlin, Aug. 12, 1885.

disc for each whole degree is prepared, and is in fact an orthographic projection of a sphere turned through an angle equal to the latitude for which it is drawn.

The proper disc for the day of observation is taken and set to the angle corresponding to the position angle of sun's axis; the disc is held at that distance from the eyepiece of the telescope, which allows the image of the sun to exactly coincide with it. The latitude is then read off; and the longitude is found by taking the longitude of centre of disc given in the table, and subtracting or adding the difference as shown in the cardboard disc.

The paper of which the above is an abstract had appended to it a set of cardboard discs suitable for actual use, and tables required for the construction of these discs.

WEDNESDAY, SEPTEMBER 16.

The following Papers were read:—

1. *On the Nature of the Corona of the Sun.*[1] *By* William Huggins, *D.C.L., LL.D., F.R.S.*

Mr. De La Rue in his address before Section A in 1872, said truly:—'The great problem of the solar origin of that portion of the corona which extends more than a million of miles beyond the body of the sun, has been by the photographic observations of Col. Tennant and Lord Lindsay in 1871 finally set at rest, after having been the subject of a great amount of discussion for many years.' (Report Brit. Assoc. 1872, p. 6.)

Professor Hastings has recently revived the theory of Delisle that the corona is an optical appearance due to diffraction. He bases his view upon the behaviour of the bright line 1474, which he saw in his spectroscope change in length east and west of the sun, during the progress of the eclipse at Caroline Island in 1883. Captain Abney's discussion of the photographs taken by the English observers shows that there was considerable diffusion during the eclipse, and that therefore the observation of Professor Hastings may have been due to a scattering by our air of the light from the brighter part of the corona, and therefore may not indicate any change in the corona itself.[2] During the time that Professor Hastings observed the change in the length of the line 1474, photographs of the corona were taken by M. Janssen, and by Messrs. Lawrance and Woods. M. Janssen says: 'Les formes de la couronne ont été absolument fixes pendant toute la durée de la totalité.'[3] The photographs taken by Messrs. Lawrance and Woods (now in Captain Abney's hands for discussion) show that the corona suffered no such alterations in form as would be required by Professor Hastings' theory during the passage of the moon across the sun.

The evidence seems to be conclusive that the corona which comes into view at a total eclipse corresponds to an objective reality of some kind existing about the sun. It is difficult on any other hypothesis to explain satisfactorily:

1. The observed and photographed spectra which vary at different parts of the corona.
2. The visibility of the planets Venus and Mercury as dark bodies when near the sun.
3. The filamentous, and especially the peculiar curved structures seen in photographs of the corona.

[1] The chief points of this discussion of the nature of the corona were suggested in a Discourse on the Solar Corona given at the Royal Institution, February 22, 1885. A more full discussion of these points will be found in the Bakerian Lecture, 1885, in the *Proc. Roy. Soc.*, vol. xxxix. p. 108.

[2] *Report of Expedition to Caroline Island*, 1883, Washington, p. 105.

[3] *Annuaire pour l'an* 1884, p. 859.

4. The close agreement of photographs taken at different times during an eclipse, and especially between photographs taken during the same eclipse at places many hundreds of miles apart.

Considering the force of gravity on the sun, and the circumstance that comets have passed unscathed through the coronal regions, we cannot regard the corona as a true solar atmosphere, that is, as a continuous mass of gas held up by its own elasticity, which extends several hundred thousand miles above the photosphere.

Up to a certain point the spectroscope gives to us definite information as to the condition of the matter about the sun which forms the corona. We learn that there is incandescent solid or liquid matter, which also reflects to us light from the photosphere. The spectrum of bright lines, which is relatively fainter and varies greatly at different eclipses, tells us of glowing gaseous matter which accompanies the solid or liquid matter. As the solid or liquid matter can exist in the corona only in the form of discrete particles of extreme minuteness, *the corona must consist of a fog, in which the particles are incandescent*, and *in which the gaseous matter does not form a continuous atmosphere.*

It has been suggested that the matter of the corona is furnished by meteoroids, and by the lost matter of the tails of comets. Though some planetary meteoroids may be thrown into the sun, and there are meteoroids which doubtless fall directly into the sun from space, yet we can scarcely suppose so steady an inflow of meteoroids as would be needed to maintain the corona in the state of permanence in which we know it to exist. A similar difficulty presents itself more strongly on the view that the corona is fed by the débris of comets' tails.

It seems to me much more probable that the matter of the corona is supplied by the sun. This view is supported by the spectroscopic evidence, for the coronal gas is shown to consist of substances which exist also in the photosphere. The structure seen in the corona is much more in harmony with the view that the matter is going up from the sun, than that it is coming down upon the sun.

We have now to consider under what dynamical conditions matter coming from the sun can take on forms such as those we see in the corona, and can pass away to such enormous distances, in opposition to gravitation, which is so powerful at the sun.

There is another celestial phenomenon very unlike the corona at first sight which may furnish a clue to the true answer to this question. The head of a large comet presents us with luminous streamers, rifts, and curved rays, which are not very unlike, on a small scale, some of the appearances which are always present in the corona. We do not know for certain the conditions under which these cometary phenomena take place, but the only theory upon which they can be satisfactorily explained, and which now seems to be on the way to become generally accepted, attributes them to electrical disturbances, and especially to a repulsive force acting from the sun, probably electrical, which varies as the surface, and not like gravity, as the mass. A force of this nature in the case of highly attenuated matter can easily master the force of gravity, and as we see in the tails of comets, blow away this thin kind of matter to enormous distances in the very teeth of gravity.[1]

If such a force of repulsion, acting from the sun, is experienced in comets, it must also be present near the sun, and may well be expected to show its power over the matter ejected from the sun. Such a force would be present if we suppose the sun's surface to possess permanently an electric potential of the same name. The sun may acquire such a potential from processes always going on, or if once charged, would doubtless remain so, and on this supposition it is not necessary to assume local electrical disturbances. But electrical disturbances must be present on the sun on a very grand scale in connection with the ceaseless and fearful activity of the photosphere. Through these disturbances the ejected matter might come

[1] *Proc. Roy. Inst.*, vol. x. p. 9. Also papers by Bredichin in the *Annales de l'Observatoire de Moscou*, and *Astr. Nachr.*, No. 2411. Also Stokes, *On Light as a Means of Investigation*, p. 70 *et seq*. See also papers by Professor Young in the *Amer. Jour. Science*; and by Mr. Proctor in *The Sun*, 3rd ed., pp. 326–427.

to have a higher potential than it possessed as forming part of the sun, and in this way too might come about some of the varying conditions upon which the observed changes in the corona may depend.

The photosphere is the seat of ceaseless convulsions and outbursts of fiery matter. Storms of heated gas and incandescent hail rush upwards, or in cyclones, as many miles in a second as our hurricanes move in an hour. Is it then going beyond what might well be to suppose that some portions of the photospheric matter, having an electric potential of the same name as that of the solar surface, and ejected, as is often the case, with velocities not far removed from that which would be necessary to set them free from the sun's attraction, should come under the action of an electric repulsion, and so be carried upwards from the sun?

If we accept this view of things, many of the coronal phenomena can be satisfactorily explained.

1. The very long coronal rays, which rest upon sufficient testimony, no longer appear improbable.

2. The peculiar curved rays within the corona may well arise from the smaller rotational velocity of the photospheric matter, which would make it lag behind as it rose from the sun, and from probably varying directions of the force of eruption combined with the repulsive force acting radially.

3. We should expect to find the largest coronal extensions over the spot-latitudes where solar activity appears to be greatest.

4. We have an explanation of the rapidly increasing tenuity of the coronal matter from the sun, as the repulsion existing between the similarly electrified particles would cause them to separate from each other.

5. The gas carried up with the solid or liquid particles would constantly vary in amount, and also in the height to which it was carried as a gas. This state of things is in accordance with the great differences observed in the spectra of different parts of the corona, and in the spectra of the same parts at different times.

6. If the corona consists of electrified particles, it may well be that the planets. especially Venus and Mercury, may have an influence in determining the mode of outflow of this electrified matter in the directions in which they happen to be. M. Trouvelot, in his report of the eclipse of 1878,[1] pointed out that the two great coronal extensions which were remarkable at that eclipse were directed respectively to the planets Mercury and Venus. General Tennant informs me that some recent calculations show that at the eclipse of 1871 the positions of Mercury and of Venus coincided with the two positions of greatest coronal extension. He considers further that at the eclipse of 1882 the combined effect of these planets is distinctly shown 'in the protruding angle at the upper left side of the engraved corona in the "Phil. Trans." 1882.'

7. It seems obvious, that, if the corona is due to a supply of matter and to forces coming from the sun, the coronal structure and the degree of extension which are produced by them at any part of the sun, would continue to be produced by these agencies at that part of the sun; and in that sense the corona would rotate. In the case of the more distant and diffused parts the rotation could scarcely be of one and the same material object, any more than in the sweep of a comet's tail at perihelion. The action of any external force, as that of a planet, would continue to be in the direction of this object, and independent of the solar rotation.

8. Eye-observations, and photographs taken with different exposures appear to show that the corona has not an outer boundary, but that it is lost in increasing faintness and diffusion. Many of the coronal particles under the influence of the electric repulsion would leave the sun, and at the same time separate more widely from each other, becoming too diffused to be longer visible.

9. This ceaseless outflow of extremely minute particles from the sun, very widely separated from each other, may possibly throw some light on another phenomenon which has not yet been satisfactorily accounted for, namely, the zodiacal light.

10. The view of the sun as an electrically charged body may throw some light

[1] *Report of Total Eclipse*, 1878; Washington, p. 93.

on the mode in which the sun acts upon our magnets. The sun being a permanently charged conductor separated from the earth also a conductor, by an insulating vacuum, would affect the distribution of the earth's electricity by its power of statical induction. As the earth rotates, currents would be set up about it to effect the redistribution of electricity required to satisfy the inducing influence of the sun. May we not find in these earth currents an explanation of some of the phenomena of the earth's magnetism? However this may be, the changes in the sun's statical induction which follow from the shooting forth of the electrified matter of the corona may well so affect the earth's currents as to bring about the disturbances observed in the needle in connection with solar phenomena.

11. If further evidence should be forthcoming in support of the observation of M. Trouvelot in 1878, and of the results of General Tennant's calculations as to influence of Mercury and Venus on the corona, there would be some probability that Venus and Mercury were permanently charged with electricity of the other name to that of the sun. If this should be found to hold good of the other planets, we should have the planets charged with one kind of electricity, and the sun charged with the opposite electricity. As we have reason to believe that the sun and planets formed originally one cosmical mass, the question may be suggested whether these charges of electricity of opposite names can have been brought about in connection with the separation of the planetary bodies.[1]

2. *On the Spectrum of the Stella Nova visible on the Great Nebula in Andromeda.* By William Huggins, *D.C.L., LL.D., F.R.S.*

This star has appeared very near the position of greatest condensation in the great nebula in Andromeda. On the evening of September 3 it presented the appearance of an orange-coloured star of from the seventh to the eighth magnitude. When viewed in a spectroscope of small dispersive power, a continuous spectrum was seen which could be traced from about C in the red to a little beyond F. There appeared great brightness from about D to about *b*, which suggested strongly the presence of bright lines in that part of the spectrum. When a more powerful spectroscope was employed, the suspicion of some bright lines in this region was strengthened, but this point could not be certainly determined.

On September 9 the star was again observed. The colour of the star appeared less strongly orange. In the small spectroscope the great brightness about D was not so marked, but the suspicion of bright lines in the region from D to *b* was confirmed; and the appearance of the spectrum in the large spectroscope left little doubt on my mind as to the existence of from three to five bright lines in this part of the spectrum.

3. *On the Bright Star in the Great Nebula in Andromeda.* By Ralph Copeland, *Ph.D.*

The author very shortly reviewed the history of the great nebula from the time of Al Sûfi, towards the close of the tenth century, to the present moment, the object being to show that there is no evidence of any actual change in the nebula itself. Passing to the recent sudden display, the author quoted various observations, beginning with Mr. Tarrant's on July 2, and ending with that of the Rev. S. H. Saxby on August 9, showing that on the whole there were some premonitory symptoms of an outbreak in or near the nucleus of the nebula. The first positive evidence of the presence of an actual star is given by Mr. J. W. Ward, who saw a star-like nucleus of about the ninth magnitude at Belfast at 11 P.M.

[1] Since this paper was read my attention has been called to the following papers by Professor Osborne Reynolds: 'On the Tails of Comets, the Solar Corona, and the Aurora, considered as Electric Phenomena,' Mem. *L. and P. Soc.*, Manchester, 3rd series, vol. v. p. 44; 'On Cometary Phenomena,' *ibid.* p. 192; 'On an Electrical Corona resembling the Solar Corona,' *ibid.* p. 202; On the Electrodynamic Effect which the Induction of Static Electricity causes in a Moving Body. This Induction on the part of the Sun, a probable cause of Terrestrial Magnetism, *ibid.* p. 209.

on August 19. Unfortunately, bad weather prevented a confirmation, and consequent announcement of this most important observation. The first published observation of the appearance of a bright star in the nebula is that of Dr. Hartwig, at Dorpat, on August 31. Estimates of the brightness were found by the writer to depend largely upon whether the effect of the nebulosity was eliminated or not. Estimates with low powers included some of the nebulosity, and made the star appear too bright. The spectrum was observed on various nights, beginning with September 1. The spectrum is almost absolutely continuous from end to end, and only on the closest scrutiny can the faintest irregularities be even suspected. The spectrum extended from W.L. 600^{mmm} to 456^{mmm}, with a maximum about 544^{mmm}. A point less obscure than the rest gave W.L. 482 (not far from F.) On September 3 Lord Crawford, in company with the author, detected a nebulous nucleus $17''\cdot0$ from the bright star. By micrometrical comparison with a neighbouring star, of which Lord Rosse gave the relative position in 1851, the author found that this nebulous nucleus now visible is really that of the Great Nebula. He then quoted from the 'Astronomical Register' of November 1882, as follows: 'A small star *s.p.* the nucleus of the great nebula in Andromeda (M. 31) has been suspected of variation by the Rev. T. W. Webb. He found the star readily visible on several occasions with a $9\frac{1}{3}$ inch "With" speculum, while at other times he found it very faint with the same instrument.' At present there is no star visible, except Dr. Hartwig's, at all corresponding to the one seen by Mr. Webb.[1] It seemed, therefore, to the author 'not unlikely that the true state of affairs is expressed by Lord Rosse in a letter dated the 9th inst., viz., "*It would appear to be the abnormal blazing out of a quick, faint, variable star, rather than the appearance of a new star which has never been seen before.*"' The spectroscopic observations are in accord with this opinion, for the spectrum is not unlike that of a variable star, while it presents no resemblance to that of a genuine blazing star like those of 1866 and 1876.

---

4. *On Solar Spectroscopy in the Infra Red.* *By* Dr. Daniel Draper.

In the year 1877 Professor Piazzi Smyth, who had just re-observed in Lisbon Brewster's three celebrated lines in the ultra red of the solar spectrum, X, Y, and Z, was in correspondence with the late Dr. Henry Draper about them, as being the furthest lines visible to the human eye in that direction, and was informed by him that his father, Dr. J. W. Draper, claimed these lines, as being the lines he had photographed so long before as in 1842, and called α, β, and γ.

Therefore it became Professor Piazzi Smyth's rather painful duty to point out that that was a mistake; for the lines α, β, and γ in Dr. Draper's photograph were far beyond the possible spectrum places of Brewster's X, Y, and Z.

But when, in a few years more, Captain Abney by improved photography, and then Professor Langley with his admirable bolometer, brought into view whole regions of lines beyond and outside Brewster's furthest X, Professor Piazzi Smyth suggested to Dr. Daniel Draper (Dr. Henry Draper having died in the interval), that the time had arrived for comparing his father's primitive photograph of 1842 with the recent discoveries, and ascertaining whether his lines α, β, and γ corresponded in any way therewith.

The answer that Dr. Daniel Draper gives, is to the effect that they do correspond, and in so remarkable a manner as to add great value to photographic testimony on a Daguerreotype plate.

5. *The Errors of Sextants as indicated by the Records of the Verification Department of the Kew Observatory, Richmond, Surrey.* *By* G. M. Whipple, *B.Sc., F.R.A.S.*

The author gave the history of the verification of sextants at the Observatory from its establishment in 1862, describing the apparatus employed devised by Mr.

[1] Unless indeed Lord Rosse's star is identical with Mr. Webb's, as was suggested by Mr. G. J. Stoney. *Note added* Nov. 6, 1885.

F. Galton, Mr. T. Cooke, and himself. Stating that the verification of the instruments comprises four stages; viz. Examination of (1) telescopes, (2) mirrors, (3) dark shades, and (4) errors of eccentricity and graduation of the arc, he detailed the various operations conducted in each stage, and finally classified the frequency of the various defects as determined from upwards of 169 instruments verified at the Observatory during the past year:—13 per cent. were defective in stage 2, 5 per cent. in stage 3, and 10 per cent. in stage 4. An analysis of all the instruments under test (4) showed that 20 per cent. had errors amounting to 30″, 30 per cent. amounting to 60″, 25 per cent. amounting to 120″, and 7 per cent. amounting to 180″; whilst only 2 per cent. fell below 20″, and were practically perfect in their gradation.

6. *On the Behaviour of First-class Watches whilst undergoing tests in the Rating Department of the Kew Observatory, Richmond, Surrey. By* G. M. WHIPPLE, *B.Sc., F.R.A.S.*

The watch-rating department of the Kew Observatory, Richmond, Surrey, has been established in order to provide makers and the public with certificates of the accuracy of the performance of good watches. The conditions of the trials adopted for three classes, A, B, C, for watches of different qualities, which are detailed below, are similar to those in use at the Geneva and Yale Observatories.

The following table will indicate the nature of the trials to which the certificates refer, the variation of rate being determined daily:—

Position of Watch during test	For Certificate of Class		
	A	B	C
Vertical, with pendant up	10 days	14 days	8 days
„ „ „ right	5 „	—	—
„ „ „ left	5 „	—	—
Horizontal, with dial up	5 „	14 days	8 days
„ „ „ down	5 „	—	—
„ at temp. 85° F.	5 „	1 day	—
„ „ 35° F.	5 „	1 „	—
Not rated (intermediate days) . .	5 „	1 „	—
Total duration of test	45 days	31 days	16 days

The results derived from of recent trials of 134 watches were given in a tabulated form, and were contrasted with similar numbers derived from foreign trials.

The number of failures to obtain certificates were—

14 per cent. for variation of rate
8 „ „ „ due to position
0·5 „ „ imperfect temperature compensation
3 „ „ other causes.

7. *On a recent Improvement in the Construction of Instruments graduated upon Glass. By* G. M. WHIPPLE, *B.Sc., F.R.A.S.*

The very clever invention of Messrs. Negretti & Zambra some years ago of running a slip of white enamel in the glass at the back of the bore of the tube of a thermometer has been most highly valued by scientists. I now submit to the notice of members of the Association a number of thermometers, eudiometers, graduated measures, &c., in which a valuable extension of the use of enamel has been carried out by Mr. Jas. J. Hicks, of 8 Hatton Garden, London.

In the case of thermometers the enamel is caused almost to surround the stem, leaving but an aperture through which to view the mercurial column. This enables the graduation to be made and the figures to be etched immediately in front of the enamel, and consequently gives them a clearness and distinctness as far superior to the ordinary tube as that is to the old-fashioned instrument with clear glass stem.

The application of the enamel to the construction of the variety of fluid measuring glasses now in use is quite new, I believe, and will be of great service in laboratories and all places where such articles are in use. In this case the enamel is not caused to almost surround the measure, but alternate segments of the sides of the glass are clear and opaque, so that a view of the fluid being measured is obtained through the spaces, and the graduations stand out distinctly on the white surfaces. Specimens of the different instruments were laid on the table.

8. *On Methods of preventing Change of Zero of Thermometers by Age. By* G. M. Whipple, *B.Sc., F.R.A.S.*

The author, having referred to methods which have been adopted at various times to rectify the rising of the zeros of mercurial thermometers by age, exhibited to the meeting certain instruments which had been annealed in accordance with a practice in use for many years in the construction of standard thermometers at the Kew Observatory. These have been made by Mr. Hicks, of Hatton Garden, who has erected special apparatus for the purpose, and apparently show that the desired result has been attained.

---

9. *On a new and simple form of Calorimeter. By* Professor W. F. Barrett.

With this instrument no corrections for the heat capacity of the vessel used or of the thermometer are necessary, and only a small correction for the loss by cooling. The bulb of the thermometer forms the cup that holds the liquid, and the stem the beam of the balance that enables its weight to be found. The temperature, T, of the warm liquid is given by the thermometer that plugs the burette as the liquid flows into the empty cup, the temperature of which is raised from t to θ. If C be the constant of the instrument and W the weight of water used, the heat lost is equal to the heat gained by the instrument, or $W(T-\theta) = C(\theta - t)$, whence

$$C = W\frac{T-\theta}{\theta - t}.$$

Hence a liquid of sp. heat S and weight W, having an initial temperature T, and which raises the temperature of the calorimeter from t' to θ' is found as follows:

$$S = \frac{C(\theta' - t')}{W_1(T_1 - \theta')}.$$

The constant C for each instrument is determined once for all and the operation then becomes a very simple and speedy one. A polished metal cap fits over the cup to prevent evaporation. The instrument is the joint invention of the author and of Mr. J. McCowan, Demonstrator of Physics in the Royal College of Science.

---

10. *On a modification of the Daniell Battery, using Iron as Electropositive Element. By* J. J. Coleman.

---

11. *On a new form of Galvanometer.* *By* Professor JAMES BLYTH, *M.A.*, *F.R.S.E.*

The author described a method of measuring electric currents by means of an instrument whose scale is graduated to equal divisions, and whose deflections are, from the intrinsic nature of the instrument, proportional to the current strength through all ranges.

In principle the instrument depends upon the mechanical action exerted by a magnetic field upon a movable conductor carrying a current. In construction it is essentially similar to the well-known apparatus, due to Faraday, for showing the continuous rotation across the lines of magnetic force of a horizontal radial conductor carrying a current and having slipping contacts at its centre and circumference. The construction will be understood from the following description.

Two bundles of permanently magnetised steel wires are made up in the form of cylinders having narrow axial holes. These are fixed with their axes in the same vertical line, separated by a narrow gap, and so that the north poles of the one set of magnets face the south poles of the other. In this gap the magnetic field is sensibly uniform and the lines of force vertical. Inserted in the gap is a thin circular disc of wood or vulcanite, having a central mercury cup and a concentric circular mercury trough at a short distance from it. A stout brass rod is provided, having a short thick copper wire rigidly attached at right angles to its lower end. Its upper end passes freely through the axial hole in the upper magnet, and is rigidly attached to the lower end of a long fine torsion wire of steel or silver, whose upper end is fixed to a suitable support. The lower end of the brass rod dips into the central mercury cup, and the outer end of the copper wire (bent down a little at right angles) dips into the concentric canal of mercury. Stout copper wires are led from the central cup and canal to binding-screws suitably placed so as to form the terminals of the instrument. The upper end of the brass rod, which projects a little above the upper magnet, carries a long pointer, which moves over a horizontal circular disc, graduated either to degrees or to show amperes directly. This disc is fixed with the torsion wire passing freely through its centre. The whole is so enclosed as to be free from air current.

The action of the instrument will be easily understood. Suppose a current sent through it. As is well known, the electromagnetic force acting on the radial current will tend to make it rotate in a horizontal plane with a uniform force. This rotation will go on till a certain angle is reached, when the moment due to the electromagnetic force is balanced by the moment due to the torsion of the wire.

Let

i = the current strength,
a = the length of the radial wire,
N = the magnetic induction,
A = the torsion constant,
θ = the angle of equilibrium,

we have

$$\tfrac{1}{2}ia^2N = A\theta\,; \quad \text{or} \quad i = \frac{2A}{a^2N}\theta,$$

showing that the current strength is proportional to the angle of deflection.

The instrument admits of several modifications. Two have been constructed in addition to that above described. In the one the permanent magnets are replaced by similarly placed electromagnetic coils, through which the current to be measured passes. In this case the square of the current strength is proportional to the angle of deflection. In the other the fixed magnets are dispensed with, and, instead, a cylindrical bundle of magnets is fixed coaxially to the brass rod, but insulated from it, so that it rotates along with the rod and radial wire. In this case the radial wire projects from the middle of the length of the magnet bundle, while the lower end of the brass rod is prolonged so as to dip into a mercury cup at a considerable distance below the lower end of the bundle. Owing to the influence of the exterior part of the circuit leading from the mercury canal to

the cup, the equation for this case is a little more complicated. With proper arrangements, however, the deflection can be shown to be proportional to the current strength.

In the instruments constructed for practical use the mercury cup and canal are so made, on the unspillable ink-bottle principle, as to preserve the mercury in case of being knocked over or even inverted.

---

12. *On the Physical Conditions of Water in Estuaries.*[1] *By* HUGH ROBERT MILL, *B.Sc., F.R.S.E., F.C.S.*

Observations have been made on the estuaries of several of the most important Scottish rivers, of the temperature and density of the water at various positions.

The temperature was observed by means of Negretti & Zambra's Standard Deep-Sea Thermometer, in a special frame devised in order to permit of the instrument being worked in shallow water and in places where the current is rapid. A modification of the slip water-bottle for the same conditions was made and found to work admirably.

Estuaries were found to be capable of division into three classes:—

1. Those in which all the salt water is withdrawn from the estuary by the ebb-tide, *e.g.*, the Spey. Here the river water freshens the surface of the surrounding sea, but affects the deep water very slightly.

2. Those in which the salt water is partially withdrawn, *e.g.*, the Tay. Here the river is brackish at low tide and the surface water of the surrounding sea is slightly freshened.

3. Those in which salt water always remains, *e.g.*, the Forth. Here at the river end the density of the water varies with the tide, but is always low; it rises rapidly in the first twelve miles and thereafter, proceeding seaward, it rises very gradually. The density of surface and bottom water approaches coincidence as the sea is neared, and the merging of the estuary into the sea is marked by a very slight decrease of density throughout the entire depth. There is no seasonal variation of density, but during a flood the freshening is perceptible all along the line in decreasing amount.

Temperature has a continually diminishing annual range as the sea is approached. In summer it falls, and in winter it rises, at first rapidly and then gradually from river to sea. The mean annual temperature at each point is the same (47·5). Bottom water is colder in summer and slightly warmer in winter than that at the surface.

13. *Further Experiments in Photo-Electricity.* *By* Professor MINCHIN.

---

14. *On the Formation of a Pure Spectrum by Newton.* *By* G. GRIFFITH, *M.A.*

In English text-books it is generally stated that Wollaston was the first to observe a pure spectrum, and that Newton did not know how to form one.

The author referred to several statements of this character (Professor W. Allen Miller, 'Chemical Physics,' 3rd edition, p. 161; Professor Roscoe, 'Spectrum Analysis,' 1869, p. 22; see also Parkinson's 'Optics,' 1859, pp. 143–45.)

These accounts are probably to be traced to a passage in Sir David Brewster's 'Life of Newton' (vol. i. p. 117 of the large edition, or p. 58 of the new and revised edition, 1875). 'Had Newton received upon his prism a beam of light transmitted through a very narrow aperture, he would have anticipated Wollaston and Fraunhofer in their fine discovery of the lines in the prismatic spectrum.' In a previous passage Brewster has described how Newton first formed a spectrum by using light which had passed through a round hole in a shutter.

[1] Published *in extenso* in the *Scottish Geographical Magazine*, Vol. II. pt. i.

Although Newton admitted light into his darkened room in this way for certain experiments, yet he was perfectly aware that the coloured image which is formed when such a beam is passed through a prism consists of innumerable coloured circles ('Opticks,' Prop. iv., Prob. 1, I), which overlap, and that the mixture of the heterogeneous rays can be diminished by making the circles of smaller diameter. The first method which he proposed for doing this was to have the hole at a great distance from the prism, so that rays coming from the centre only of the sun would be used.

Then follows this passage: 'But that those circles may answer more distinctly to that hole, a lens is to be placed by the prism to cast the image of that hole upon the paper. If this be done it will not be necessary to place that hole very far off; no, not beyond the window.'

He then describes fully how this is to be carried out practically.

This passage is followed by another, which, strange to say, has escaped the notice of Brewster and many others, 'Opticks,' p. 59, 2nd ed. 'Yet instead of the circular hole (F), 'tis better to substitute an oblong hole shaped like a long parallelogram, with its length parallel to the prism (A, B, C). For if this hole be an inch or two long, but a tenth or twentieth part of an inch broad, or narrower, the light of the image "*i.e.* the spectrum" (*pt*) will be as simple as before or simpler, and the image will become much broader and, therefore, more fit to have experiments tried in its light than before.'

He also says that a triangular aperture may be used, the base of the triangle being about the tenth of an inch, its height an inch or more. In the spectrum formed by light passing through such an aperture, he says that the bases of the triangular images overlap a little, but their vertices do not.

In all these experiments the prisms were placed at the angle of minimum deviation. The lens was generally placed at a distance from the aperture equal to double its focal length, and the screen at the same distance from the lens. The prisms are carefully described; one is stated to have 'had some veins running along within the glass from one end to the other, which scattered some of the sun's light irregularly.' Others are described as being 'free from veins.' He also used prisms filled with rain-water. In one of his letters to Oldenburg, Horsley's 'Newton,' vol. iv. p. 343, he refers to a crystal prism. This must have been rock crystal.

Very ordinary prisms will show the Fraunhofer lines. Prof. Rood using the prisms of an ordinary candelabrum found no prism among twelve which did not show several lines. It seems now impossible to account with certainty for their not being seen by Newton; it certainly was not for the reason given by Brewster. Nor probably was it due to the inferior quality of the glass or workmanship of the prisms. Newton used an assistant for observing the spectra in certain experiments. 'Opticks,' p. 110 (2nd ed.) 'An assistant, whose eyes for distinguishing colours were more critical than mine, did by right lines,' . . . 'drawn across the spectrum, note the confines of the colours.' It is possible that this assistant may have seen the lines, but Newton's attention was not called to them, and their existence was not recorded by him.

For full details of many of Newton's experiments it is necessary to refer to the 'Lectiones Opticæ,' which were not published until after Newton's death. They were delivered in the years 1669–71, at Cambridge, where the original manuscript was deposited.

In one of the early lectures he describes his observation of the spectrum of the planet Venus. 'The object glass of a seven-foot telescope, its aperture being two inches and more broad, to transmit a sufficient quantity of rays,' received the light of the planet, and formed upon a paper at the distance of seven feet an image 'like a lucid point.' A prism being then interposed, the spectrum formed is described as 'a very fine line, though not very bright, however very easily to be discerned.' He then remarks: 'And I believe the same thing might be observed of stars of the first magnitude, as of Sirius, especially if a lens be used four or six inches broad, that it may transmit many rays.' In a subsequent page it is stated that this experiment had been successfully tried.

This interesting observation is given, in terms which are substantially the same, in a letter addressed to Oldenburg, and dated Cambridge, April 1672 (Horsley's 'Newton,' iv. p. 311). In the letter the spectrum of Venus is described as a 'long splendid line.'

In conclusion, the author referred to the brief but correct account of Newton's experiments described in the early part of the paper, by Lloyd in his 'Undulatory Theory,' and in Verdet's Works, iii. p. 253.

---

15. *On the Use of Bisulphide of Carbon Prisms for cases of Extreme Spectroscopic Dispersion, by* Professor C. PIAZZI SMYTH; *and their Results in Gaseous Spectra, commented on by* Professor ALEXANDER S. HERSCHEL, *M.A., F.R.S.*

The serious loss of light which occurs by absorption in long trains of dense glass prisms was attempted to be diminished by the first author using, in place of the usual flint-glass prism between two correcting crown-glass ones, a bisulphide of carbon prism with a refracting angle of 104°. A train of such compound fluid prisms of 2·1 inches optic apertures, together with two simple flint-glass prisms, each of 64° refracting angle, dispersed the spectrum between A and H over an angle of about 60°. The spectrum so formed was examined with an inspecting telescope of 2·25 inches aperture, 32 inches focal length, and of magnifying power 36. About one-seventh of the whole length of the spectrum could be commanded at one time by the range of the micrometer-screw which moved the inspecting telescope in angle, without resetting the prism train to minimum deviation for the next adjoining portion of the spectrum.

After overcoming the tendency of the interior glass faces to contract a film from the cement used in the prisms, by repeated washings, the well-known difficulties of inequality of temperature in the fluid prisms, disturbing their homogeneity and altering the total dispersion of the train, had then to be contended with, and were obviated sufficiently for relative measurements by the use of non-conducting coverings of the prisms, and by guarding carefully in each set of observations against accidental changes of temperature in the room.

With the spectroscope so arranged the first electric spectrum of a vacuum tube examined, was that of oxygen gas. The four distinct lines of the so-called compound spectrum of the gas were identified, and three of them proved on examination with the instrument's high dispersive power to be really compound, each of the three being resolved into a delicate line-triplet. Three similar line-triplets in regular configuration with these in neighbouring parts of the spectrum were also found, while a strong oxygen line, in addition to other single lines of the spectrum, was detected in the ultra-red at a distance from the ordinary field of chromatic light in that direction greater than that of any elementary gas-spectrum line yet ocularly measured.

Of the numerous array of lines produced in hydrogen-tubes which have been ascribed to hydrogen, 1,616 lines were well seen and measured, most of them extremely sharp and beautifully precise lines. Of these 1,442 are in the space where 448 such lines are recorded in the hydrogen line catalogue of this gas's compound spectrum in the Report and tables of the wave-lengths of the elements, presented last year by the Spectroscopic Committee of the British Association,[1] 20 are beyond the violet, and 154 are beyond the red limit of the range of the same catalogue in that Report.

As another example of the great resolving and defining powers of the bisulphide of carbon prism spectroscope, it may be noted that in a single fluting of the compound spectrum of nitrogen near the solar line D, in which twenty linelets and haze-bands are figured in the extensive map of that spectrum recently communicated to the Imperial Academy of Sciences of St. Petersburg by Dr. Hasselberg, 161 sharp lines were seen and mapped with the train of fluid prisms, while only three wave-lengths of the leading edges in the same fluting are noted

[1] *British Association Reports*, 1884, p. 390.

in the table of the compound spectrum of nitrogen of the Report already quoted. Again, in place of the 115 wave-lengths of haze-band edges, noted as forming the whole fluted or compound spectrum of nitrogen in that Report, scarcely less than 7,000 lines of the same spectrum have been so clearly seen and distinguished in it with the bisulphide of carbon spectroscope, as to be all mapped and delineated on the lithographic plates of the results obtained with this spectroscope, which will be published in the next, now nearly completed, volume of the Transactions of the Royal Society of Edinburgh.

The measurements of this gas-spectrum's exceedingly full crowd of lines were rendered possible in great measure by end-on vision-tubes of nitrogen of very superior purity and brightness, produced for the author by Mr. C. Casella, the electric excitation of the tubes being also brought under exceptionally regular control by a new battery and five-inch spark induction-coil specially supplied to him for this purpose by Mr. Alfred Apps, of London.

A fourth example of the spectroscope's great optical efficiency was its complete disentanglement of the remarkable web of fine lines forming the green band of the electric spectrum of carbonic oxide. When seen through a spectroscope of this power a curious crossing presents itself near the band's brighter edge, arising from the concurrence there, apparently, of two really distinct but not easily separable series of very similarly arranged linelets, of which the band's line-cluster must at least consist. In Professors Angström and Thalén's drawing of it ($1\frac{1}{4}$ inch long) in their 'micrometric measurements,'[1] the details delineated only amount to fourteen separately represented light maxima of the gradually decreasing band. But with the expansion of this length which the micrometer-screw's automatic tracing point of the bisulphide of carbon prism spectroscope effected on its paper page, from $1\frac{1}{4}$ inch to 26 inches (corresponding in its scale to nearly 4 inches for the interval between the two sodium D lines, and to about 220 feet in length for the whole visible extent of the spectrum from A to H), no haziness of light was any longer to be seen, but instead of it a series of 43 sharp linelets in this space were plotted accurately in their true relative positions by the recording pointer on the paper.

Even with this automatic means of registration, however, the task of projecting the prodigious multitude of sharp lines observed in the several different gases submitted to examination, demanded the writer's available diligence towards this end too constantly to allow him to give special attention to any harmonic or other numerical relations which may exist among the abundant data thus collected, although researches of this kind hereafter are not proposed to be omitted. A notable example of the probable prevalence of such relations, and a striking corroboration of the clear vision and accuracy reached in the projections, presented itself, however, in the mapped places just now described of the 43 carbonic oxide green-band linelets. A map of this band's evidently complete resolution into all its component linelets was sent for inspection to Professor Herschel, and it immediately suggested to him a simple law of progression which embraces all the lines mapped upon the sheet (of which a figure accompanied this paper) of this band's visible components; if, at least, duplicity of more than half the lines of one of its ranks be disregarded, which is so extremely close that it scarcely yet furnishes any material occasion for the paired lines' separate descriptions. The exactness of the surmised progression's agreement with the record is all the more noteworthy when it is stated that the latter includes measurements of intervals between some of its lines not exceeding the 50th part of the micrometer interval between the two sodium lines, and that within about that diminutive quantity also it everywhere agrees with the presumed line-places of the theoretical progression, whose range yet extends to many intervals between the sodium-lines along the linelet ranks.

The rank of split-lines of the green carbonic oxide band has successive intervals beginning from its first line which forms the leading (or least refrangible) edge of the green band, represented by the natural numbers, 1, 2, 3, 4, &c., with a space between the first two lines, or an arithmetical difference between the intervals of the succeeding lines, of about two British, or three-quarters of a metrical wave-

[1] *Transactions of the Royal Society of Upsala*, 1875.

number unit. Its procession remains in sensibly exact agreement with this rule to the seventeenth and eighteenth lines, still visible, and measured in the map. But it grows quickly fainter from the sixth line onwards, and presents signs of division and duplicity in its lines from about the ninth line onwards.

The other rank of lines (which completes the whole group) is identical in its intervals with the first, but its lines are not double, and, fading more slowly in brightness than those of the other rank, they form in the open part of the band its strongest array or main-line troop. Almost exact coincidence occurs of its tenth line with the eleventh line of the other rank, and the line intervals being there pretty wide, an appearance of crossing of the two series and of condensed brightness in the nearly doubled line forms the easily recognised and marked feature of the band already mentioned, not very far from its bright edge. Nearer to the edge than this the lines of the two ranks, nearly equal to each other in brightness, are unaccordant and intermixed in place with little apparent signs of orderly relation. But another crossing-point yet happens here (an arithmetical consequence of the former one), where the two ranks have a spectral line in common with each other. This is the leading line of the second or single-line rank, which coincides and is, as far as the observations can determine, identical with the fifth line of the projecting band-edge or split-line rank.

The new common line of the two progressions is not brighter by superposition than adjoining lines, preceding and following it, of the two ranks in which it falls; but the second rank of lines takes its origin in the fifth line from the band-edge or front line (inclusive) of the other rank, and being thus four intervals or ten unit-spaces $(1+2+3+4)$ distant from that edge, all its lines fall thus far in advance of those corresponding to them in the other leading or projecting file. It thus happens that its tenth line, instead of coinciding with the other file's tenth line, is advanced ten unit spaces of the progression from it, and falls into agreement, therefore, with the eleventh line of that rank, which is also ten unit spaces distant from the last preceding or tenth line of its serial progression, as the two lines are found to do quite accurately at the crossing-place of the band. For in the faithfully depicted map, the single or main line at this point exactly hides or takes the place of one of the two half-lines, which together should form a close pair of the split-line spectrum at that place. Both the great accuracy of the observations and the perfect correctness of the presumed law of line-interval succession seem to be alike proved, and established satisfactorily by this unintentional and yet most remarkably exact agreement.

The two partial linelet spectra of this band, as far as they were measured, agree with each other when superposed rather more perfectly than with the theoretical progressive points computed for them on the micrometric scale of the map; but this is to be expected, as the scale of prismatic dispersion, or of micrometric parts, is not identical with that of wave-numbers, in relation to which alone the rule of succession of the lines in intervals forming an arithmetical progression is in all probability exactly true. But the real identity of the formula, whatever it may be, for the two partial spectra is shown quite free from any such deceptions by confronting a copy of the lines of one with the lines of the other spectrum on the map, and observing the almost perfect superpositions which this yields, in each and every line. It seems allowable to speculate whether the occasional choice of valency which chemists find it necessary to ascribe to carbon, between bivalency and tetravalency in its varying power of forming saturated compounds, may not be connected with this twofold repetition, which here certainly exists, of one and the same rank of spectral lines in a single spectral band, thus shown by one of that element's abnormally saturated compounds under very vigorously electrified conditions.

Section B.—CHEMICAL SCIENCE.

President of the Section—Professor H. E. Armstrong, Ph.D., F.R.S., Sec.C.S.

THURSDAY, SEPTEMBER 10.

The President delivered the following Address:—

In the Chemical Section of the British Association for the Advancement of Science the advancement of chemistry throughout the British Empire must be a subject of commanding interest. Signs of such advancement are not wanting:—the rapid establishment of science colleges in one after another of our large towns; the establishment of the Society of Chemical Industry, which now, only in the fifth year of its existence, numbers over 2,000 members; the granting of a Royal charter to the Institute of Chemistry; the changes introduced at the London University in the regulations for the D.Sc. degree; the report of the Royal Commission on Technical Education, in which the value to chemical manufacturers of advanced chemical knowledge is so fully recognised; the important conference on education held at the Health Exhibition last year; the recent agitation to found a teaching university in London with adequate provision for research—surely all these are signs that the value of higher education must and will, ere long, be generally recognised.

The neglect of chemical research in our British schools has often been forcibly commented upon—of late, especially, by an eminent past-President of this Section, Dr. Perkin, whose opinion is of peculiar value, as he is not only world-renowned as a chemist, but also as a manufacturer: indeed, as the founder of two distinct important chemical industries. There can be no doubt of the fact and of the dire consequences to our country of such neglect: how is it, then, that such pronounced complaints have been so coldly received; that hitherto they have produced comparatively so little effect; and that such slight encouragement is being given to those who, notwithstanding the many difficulties in their way, have steadfastly devoted themselves to research work? I question whether the value of such work has yet been brought home to teachers generally, let alone the public: the '*cui bono?*' cry is almost invariably met by pointing to some discovery of great pecuniary value as the outcome of research. This argument educationalists very properly refuse to recognise. Too little has been said as to the cause of the neglect so bitterly and properly complained of. Hence it is that I propose again to take up what many may regard as a somewhat threadbare theme.

Everyone will agree with Professor Sir Henry Roscoe, who in his address last year to this Section said 'that those who are to become either scientific or industrial chemists should receive as sound and extensive a foundation in the theory and practice of chemical science as their time and abilities will allow, rather than they should be *forced prematurely*'—the italics are mine—'into the preparation of a new series of homologous compounds, or the investigation of some special reaction, or of some possible new colouring matter, though such work might doubtless lead to publication.' We must also all cordially agree with him that the aim should be, as he tells us his has been, 'to prepare a young man by a careful and fairly complete general training to fill with intelligence and success a post either as teacher or industrial chemist, rather than to turn out mere specialists, who, placed under

other conditions than those to which they have been accustomed, are unable to get out of the narrow groove in which they have been trained.' If it were necessary to show that Sir Henry Roscoe is a believer in research in its proper place, ample proof would be afforded by his statement, 'that, far from underrating the educational advantages of working at original subjects, he considers this sort of training of the highest and best kind, but only useful when founded upon a sound and general basis.'

But I venture to think that something has to be added in order to completely define the position of those who deplore the slight amount of original work which is being done in British laboratories. We maintain that no one can really '*fill with intelligence and success* a post either as teacher or industrial chemist' who has not been trained in the methods of research; and that, owing to the neglect of research, the majority of students are of necessity trained in a narrow groove. The true teacher and the industrial chemist are daily called upon to exercise precisely those faculties which are developed in the course of original investigation, and which it is barely possible—many would say, perhaps with justice, it is impossible—to sufficiently cultivate in any other manner. In a works the *chemist* is scarcely required as long as all goes well. The quality of the materials used or produced can be controlled by purely routine processes of analysis by the works analyst, or by well-trained laboratory boys. But things never do go well for any long period of time: difficulties are always arising; obscure points have to be investigated; and, if the manufacturer understand his business, improvements have to be effected—which cannot be done unless the conditions under which he is working be understood, as well as the character of the changes which are taking place. Investigation is therefore necessary at every step. No amount of instruction, such as is ordinarily given, in the mere theory and practice of chemical science will confer the habits of mind, the acuteness of vision and resourcefulness required of an efficient chemist in a works, any more than the mere placing of the best tools in a workman's hands will make him a skilful operator.

Such being our position, we maintain that it is essential to make research an integral portion of the student's course in every college which pretends to *educate chemists.* It will not suffice occasionally to set a promising student to investigate, but a number of students, as well as the staff, must always be engaged in original work: in fact, *an atmosphere of research must pervade the college.* It cannot be too clearly recognised that it is this which characterises and distinguishes the German schools at the present time. The student does not learn so much from the one special piece of work with which he is occupied, but a number of his fellow-students being also similarly engaged, the spirit of inquiry is rife throughout the laboratory: original literature is freely consulted, and they thus become acquainted with the methods of the old masters; vigorous discussions take place, not only in the laboratory, but also at that most useful institution, the 'Kneipe'; the appearance of each new number of the scientific periodicals is keenly welcomed;—in fact, a proper spirit of inquisitiveness is awakened and maintained, until it gradually becomes a habit. Probably there is less actual routine teaching done by the staff in the German schools than in our own. I am proud to own my indebtedness to one of them, and I can without hesitation say that I never truly realised what constituted the *science* of chemistry until I came under its influence.

But to realise the state which I have pictured—*to create an atmosphere of research in our science colleges in order that it may be possible for our students to obtain complete training in chemistry,* several things are required. In the first place, it will be necessary that the students come to them better prepared than they are at present: as a rule they are so ill-prepared that it is very difficult, if not impossible, in the time at disposal to give such preliminary instruction as is indispensable before higher work can be attempted. Their mathematical knowledge is so ill-digested that it is more often than not necessary to begin by teaching simple proportion, and they look aghast at a logarithm table. They cannot draw—so far have we advanced in our civilisation that the subject is more often than not an 'extra' in our schools. They understand a little French; but German, which may almost be called the language of modern science, is indeed an unknown tongue

to them. I do not complain of their want of knowledge of science subjects, but of the unscientific manner in which they have been trained at school, and especially of the manner in which their intellectual faculties have become deadened from want of exercise, instead of developed and sharpened. Too many have never acquired the habit of working steadily and seriously; they have not learnt to appreciate the holiness of work,[1] so that they render the office of teacher akin to that of slave-driver instead of to that of friend. What is perhaps worst is their marked inability, often amounting to downright refusal, either to take proper notice of what happens in an experiment or to draw any logical conclusion from an observation. Man is said to be a reasoning being, but my experience as an examiner and teacher would lead me to believe that this fact is altogether lost sight of by the average schoolmaster, who appears to confine himself almost exclusively to the teaching of hard dry facts, and makes no attempt to cultivate those very faculties which are supposed to characterise the human race; or he is so ill-prepared for his work that he fails to understand his duty. These are harsh words, but the evil is of such magnitude that it cannot be too plainly stated; those who, like myself, are brought full face to it fail in their duty if, when opportunity occurs, they do not take occasion to call attention to its existence.

Probably the only remedy—certainly the most effectual, and that which can be most easily applied—is the introduction of a *rational system* of practical science teaching into all our schools, whatever their grade; one effect would be that all the school subjects would of necessity soon be taught in a more scientific manner. I am not one of those who would eschew the teaching of classics, and I do not wish to see science teaching introduced into schools generally in order that the students who come to me may already have gained some knowledge of science: under existing circumstances I prefer that they shall not; but I desire its introduction because the faculty of observing and of reasoning from observation, and also from experiment, is most readily developed by the study of experimental science: this faculty, which is of such enormous practical value throughout life, being, I believe—as I have said elsewhere—left uncultivated after the most careful mathematical and literary training. No one has stated this more clearly than Charles Kingsley. We are told that, speaking to the boys at Wellington College, he said: 'The first thing for a boy to learn, after obedience and morality, is a habit of observation—a habit of using his eyes. It matters little what you use them on, provided you do use them. They say knowledge is power, and so it is—but only the knowledge which you get by observation. Many a man is very learned in books, and has read for years and years, and yet he is useless. He knows *about* all sorts of things, but he can't *do* them.' This is precisely our complaint—the average schoolboy may know a good deal *about* things, but he can't *do* them. The ordinary school system of training does not, in fact, develop the 'wits,' to use a popular and expressive term for the observing and reasoning faculties; but it is certain that the wits require training. It is because the teaching of experimental science tends to develop the wits that those among us who know its power are so anxious for its introduction. This cannot be too clearly stated, the popular view—to judge from newspaper discussions—being apparently that science is to be classed with 'extras': that it is good for those who can afford it, but can be dispensed with by those who cannot. This undoubtedly is true of the 'science' which is taught the specialist, and I fear even of much of the 'science' which is at present taught in schools: let us hope that ere long other views will prevail when the object which it is sought to gain by teaching science is made clear.

While blaming the schoolmaster for his neglect, it must not be forgotten that the teaching of sciences in schools meets with comparatively little encouragement at the hands of our examining bodies and the universities. Again, examinations are too often entrusted to those who have no educational experience, and with

[1] In my experience, the behaviour of ordinary day male students is, in this respect, particularly striking in comparison with that of female and evening students: the evening students, who come with a desire to learn, and the female students are invariably most attentive, and make the fullest use of the opportunities afforded them.

most unfortunate results: in no case, probably, is inexperience so inexcusable as in an examiner. Too often, also, the examinations are in the hands of pure specialists, who take too formal a view of their duty, and expect from boys and girls at school as much as from their own students, who are older and devote more time to the work. Such examiners are prone to discourage science by marking too severely; and as their questions govern the teaching, instruction is given in schools without due reference to educational requirements, and in a purely technical style: this, I fear, is the effect of some of the universities' local examinations.

I have it on good authority that the recent changes in the scheme of the examinations for admission at Sandhurst have forced one large school, well known for the attention paid in it to the teaching of science, to cease to give instruction in science to those of its pupils who propose to compete at these examinations, at once on their deciding to do so. Then, not only are the science scholarships at the universities few in proportion, but the great majority of students pass through their university career without being called upon to gain the slightest knowledge of physical science: yet, more often than not, the teachers are chosen from these. A large proportion become clergymen, and considering the demands upon them and the unbounded opportunities which they have of imparting useful information, there cannot be a doubt that to no other class of the community is a knowledge of natural science likely to be of more value.[1] Let us hope that the time is near when our universities will no longer be open to this reproach.[2] Whatever steps they may elect to take, it is before all things important that it be not forgotten that their main purpose must be to influence the schools, so that experimental science may be used as an educational weapon at the most appropriate time, and not when the faculties to be fashioned by it have become atrophied through neglect, as I fear is too often the case, ere the university is reached.

We must carefully guard against being satisfied with the mere introduction of one or more science subjects into the school curriculum: some of those who strenuously advocate the introduction of science teaching perhaps do not sufficiently bear this in mind. Chemistry, physics, &c., may be—and I fear are, more often than not—taught in such a way that it were better had no attempt whatever been made to teach them. I hold that it is of no use merely to set lads to prepare oxygen, &c., or to make experiments which please them in proportion as they more nearly resemble fireworks; and it is not the duty of the schoolmaster to train his boys as though they were to become chemists, any more than it is his duty to fit them to enter any other particular profession or trade: the whole of the science teaching in a school should be subservient to the one object of developing certain faculties. Unfortunately, two great difficulties stand in the way at present—viz. the want of suitable books and of a rational system of teaching science from the point of view here advocated; and the requirements of the universities and other examining bodies. Both books and examinations are of too special a character: they may suit the specialist, but do not meet educational requirements. I have already somewhat fully expressed my views on this subject in a paper read at the Educational Conference in London last year. Although much more might be said, I will only now call attention to the important service which we may render in removing these difficulties.

[1] 'I sometimes dream,' said Kingsley, 'of a day when it will be considered necessary that every candidate for ordination should be required to have passed creditably in at least one branch of physical science, if it be only to teach him the method of sound scientific thought.'

[2] I learnt with the most lively satisfaction, but a few days ago, that Dr. Percival, the late head-master of Clifton College, speaking at a meeting of Convocation at Oxford last term, said: 'If twenty years ago this university had said: from this time forward the elements of natural science shall take their place in responsions side by side with the elements of mathematics, and shall be equally obligatory, you would long ago have effected a revolution in school education.' This remark elicited some warm expressions of approval. Dr. Percival, I am sure, has the cordial approval of all science teachers, and he will earn their gratitude, and deserve that of the public at large, if he can succeed in inducing his university to take action in accordance with his enlightened views.

The reform most urgently needed, in which, as members of the community, not merely as chemists, we are all most interested, is the introduction of some system which will ensure a proper training for teachers. Engineers, lawyers, medical men, pharmacists, have severally associated themselves to found institutions which require those who desire to join the profession to obtain a certain qualification; even chemists are seeking to do this through the Institute of Chemistry. But schoolmasters, although members of what is probably the most responsible, onerous, useful, and honourable of any of the professions, have as yet neither made, nor shown any inclination to make, a united effort to ensure that all those who join their profession shall be properly qualified. Surely the time has come when the subject must receive full public attention; the country cannot much longer remain content that the education of all but those of its sons and daughters who come within the province of the School Board should be carried on without any guarantee that it is being properly conducted.

Glaring as are the faults in the existing school system, and although it rests with the universities and other teaching and examining bodies—if the public do not intervene—to prescribe a proper course of instruction for potential schoolmasters and to enforce a rational system of training all the mental faculties, we science teachers may meanwhile do much by introducing more perfect methods into our own system of teaching. The students attending our courses belong to various classes: some will become chemists, and require the highest and most complete training; others will be teachers in colleges or schools; many will occupy themselves as consulting chemists or analysts; many others will have to take charge of manufacturing operations in which a knowledge of chemistry is of more or less direct importance and value; not a few will become medical men; and a large proportion, let us hope, will be those who have no direct use for chemistry, although the knowledge will be of great service to them in many ways: among such we may include architects and builders, engineers, farmers, and even country gentlemen. Have we sufficiently considered the several requirements of all these various classes? I submit, with all due deference, that we have not! Our attention has been too exclusively directed to the training up of the future analyst; the instruction has been of too technical a character.

I know it is rank heresy to say so, but I maintain that in future far less time must be devoted to the teaching of ordinary qualitative and quantitative analysis, and that *technical instruction* as now given in these subjects must find its place later in the course. Our main object in the first instance must be to fully develop the intellectual faculties of our students; to encourage their aspirations by inculcating broad and liberal views of our science, not an infinite number of petty details. We must not merely teach them the principles and main facts of our science, but we must show them how the knowledge of those facts and principles has been gained; and they must be so drilled as to have complete command of their knowledge. The great majority will not be required to perform *ordinary* analyses, either qualitative or quantitative; it will be sufficient for them to have gained such an amount of practical experience that they thoroughly understand the principles of analysis; that they shall have learnt to appreciate the sacredness of accuracy; and that they shall have acquired sufficient manipulative skill to be able when occasion requires to carry into execution the analytical process which their text-books tell them is applicable, and even, if necessary, to modify the process to suit circumstances.

Chemistry is no longer a purely descriptive science. The study of carbon compounds and Mendeljeff's generalisation have produced a complete revolution! The faults in our present system are precisely those which have characterised the teaching of geography and history, and which are now becoming so generally recognised and condemned; in fact, no better statement of the manner in which I conceive chemistry should be taught could be given than by broadly applying to the teaching of chemistry what was said by Professor Seeley, at the International Conference on Education last year, in an important paper on the teaching of history.

The necessity for some change must, I venture to think, be patent to all thought-

ful teachers, and especially to those who are called upon to fulfil the painful duties of an examiner. The railway book-stalls have made us acquainted with 'Confessions' of all sorts, but if the 'Confessions of an Examiner' were to be written they would be far more heartrending than any. The examiner in chemistry, let him go where he will, scarcely dare ask a question to which the answer cannot be directly read out from a text-book. He will be told 'that such and such a compound is formed by the action of so and so upon so and so,' but he will usually find blank ignorance of the phrase 'by the action of,' and as to the mode of performing the operation. The examiner would, however, be bound to agree with the teacher that it is almost impossible to induce students to seek information outside the lecture-room, and except in the ordinary cram text-books, and that it is hopeless to expect them to devote attention to anything unless it will pay in a subsequent examination—in fact that the old university spirit of acquiring knowledge for its own sake is almost unknown among our science students. Herein lies one of the teacher's most serious difficulties, as he is more often than not bound to teach in a particular way, or to teach certain subjects, in entire opposition to his own views, in order to qualify his students to pass a particular examination: for example, many of our colleges now distinctly state that their courses are intended to qualify students to pass the examinations of the London University, and hence they are governed by the requirements of that university, which vary more or less as the examiners are periodically changed. The examiner, on the other hand, is often placed in a difficult position: it is clear to him that the system under which the students he is called upon to examine have been taught is a bad one: yet he feels that he has no right to set questions such as he honestly believes should direct the teaching into proper channels, because he knows that the teacher is immovable, and it is not fair to make the examinees the victims of a system for which they are not responsible. Hence, perforce, the teacher goes on teaching badly and the examiner examining badly. Difficulties of this kind are bound to make themselves felt at a transition period like the present, and will only disappear if we recognise the grave responsibility which rests upon ourselves and improve our methods of teaching and our text-books: these latter, in too many instances, are unsuited to modern requirements, and are being made worse by stereotyping, and the practice which is gradually creeping in of merely changing the date on the title page and the numeral before the word 'edition,' thus engendering the belief that the information is given up to date.

Both in teaching and examining two important changes ought forthwith to be made: our students ought at the very beginning of their career to become familiar with the use of the balance; and the imaginary distinction between so-called inorganic and organic compounds should be altogether abandoned. I do not mean that students should be taught quantitative analysis as ordinarily understood, but that instead of endeavouring to make clear to them by explanation only the meaning of terms such as equivalent, for example, we should set them to perform a few simple quantitative exercises in determining equivalents, &c. It can easily be done, and terms which otherwise long remain mythical acquire a real meaning in the student's mind. That the elements of the chemistry of carbon compounds do not find a place at a very early period in the course of instruction is one of those riddles connected with our system which it is impossible to answer. Attention was once pithily directed to the fact in my hearing by a scientific friend—not a chemist—who said he had often felt astonished that, although he had learnt a good deal of chemistry, the chemistry of the breakfast-table was practically a sealed book to him, common salt being the one object of which he felt he knew something.

I may here urge that there is one great error which we *must* avoid in the future, that of overworking our students, in the sense of obliging them to pay attention to too many subjects at a time. This is done more or less, I believe, in all our science schools, and medical students are peculiarly unfortunate in this respect. It is to some extent necessitated by the deficient preliminary education of our students; but I believe that I am justified in stating that it is also partly, perhaps mainly, due to the fact that the curriculum is too often imposed by lecturers who are directly interested in the attendance of students at their lectures. This is one of the great difficulties in the way of higher education, and the continuance of the

evil is probably in a measure due to inappreciation of what constitutes higher education and culture: neither consist in a smattering of knowledge of a variety of subjects such as is too often required at present.

The more general appreciation of the value of science undoubtedly depends to a considerable extent on improvements such as I have indicated being introduced. When such is the case, we may hope that a large number of students will enter our chemical schools, not with the intention of becoming chemists, but because it will be recognised that the training there given is of high educational value, and that a knowledge of chemistry is of distinct service in very many avocations.

We may also hope that it will be possible ere long to teach chemistry properly to medical students. Seeing that the practice of medical men largely consists in pouring chemicals into that delicately organised vessel the human body, and that the chemical changes which thereupon take place, or which normally and abnormally occur in it, are certainly not more simple than those which take place in ordinary inert vessels in our laboratories, the necessity for the medical man to have a knowledge of chemistry—and that no slight one—would appear to ordinary minds to stand to reason; that such is not generally acknowledged to be the case can only be accounted for by the fact that they never yet have been taught *chemistry*, and that the apology for chemistry which has been forced upon them has been found to be of next to no value. No proof is required that the student has ever performed a single quantitative exercise; and I have no hesitation in saying that the examinations in so-called practical chemistry, even at the London University, are beneath contempt: after more than a dozen years' experience as a teacher under the system, I can affirm that the knowledge gained is of no permanent value, and the educational discipline *nil*. Here the reform must be effected by the examining boards: it is for them to insist upon a satisfactory preliminary training, and they must so order their demands as to enforce a proper system of practical teaching; and if chemistry is to be of real service to medical men more time must be devoted to its study. Physiological chemistry is taught nowhere in our country, either at the universities or at any of our great medical schools; let us hope that the publication of works like those of Gamgee and Lauder Brunton may have some effect in calling attention to this grievous neglect of so important a subject.

Having dealt with the educational aspect of the question, let me now briefly refer to some other difficulties which seriously hinder research. It has been more or less openly stated that the teachers in our chemical schools might themselves do far more. Is this the case? I do not think so; I believe it is not the staff, in most cases, who are primarily in fault. Under our peculiar system of placing the government of science schools in the hands of those who have little, if any, experience as educationalists and little knowledge of or sympathy with science, the appointments are sometimes made without the slightest reference to capability of inciting and conducting original investigation, and without any proof having been given even of a desire to promote higher education in the only possible way—by research; nevertheless, experience shows that, as a rule, fair use is made by teachers of their opportunities. The opportunities afforded us are indeed few. In the first place, the amount of actual routine teaching we are called upon to perform is very considerable, many of us having to conduct evening as well as day classes; and the work is often of the most harassing description, owing to the want of interest displayed by the students. The assistance provided is also too often inadequate, and much which should be done by assistants is therefore thrown upon the principals. Higher work under these conditions is practically out of the question, not so much because it is impossible to snatch at intervals a few hours per week, but because the attention is so much taken up in the preparation of lectures and laboratory and tutorial teaching that it is impossible to secure that freedom of mind and concentrated attention which are essential to the successful prosecution of research. Bad, however, as is often the position of the principals, that of the junior staff is usually far worse. During official hours they are entirely occupied in tutorial work, and what little energy remains must more often than not be devoted to coaching or literary work, to supplement the too modest income which the salary attached to their official position affords. Under these circumstances, it is remarkable that so much enthusiasm should prevail among

them on the subject of research. The tradition which prevails in the German schools, that the junior staff are bound to find some time for original work, is almost unknown in this country, and too often difficulties are raised, rather than facilities afforded, when the desire is manifested: we do not, in fact, sufficiently honour the assistant as the potential professor. It has also often struck me as remarkable, and it must have struck others who understand the German system, that in this practical country we have not adopted that cheap luxury—the Privat-Docent, who costs nothing and exercises a most important function in promoting higher education. The explanation of this and many other anomalies lies in the fact that very few among us realise what a university is: a clear exposition of the Scotch and German systems would be of great value in these days of new universities and university colleges.

I believe that in most, if not all, of the German chemical schools a private research assistant is placed at the disposal of the professor. Will this ever be the case here? The want of material assistance is not only felt in this respect, however: few of our chemical schools are really efficiently equipped; most of them are seriously in want of larger and more expensive apparatus, of suitable specimens, &c.; the annual grant barely suffices for the purchase of the ordinary chemicals and the payment of unavoidable current expenses, so that, as a rule, nothing remains to meet the expenses of research work—*i.e.*, of higher education. In point of fact, nearly all of those who are engaged in research are doing so at their own expense; important assistance, for which we cannot be too thankful, is indeed received from the various research funds, but the proportion which the grants bear to the total sum expended is not large. I am sure we all recognise that each one of us is bound, according to his abilities and the opportunities he has, to add to the stock of knowledge, and that the keenest intellectual pleasure is derived therefrom; but it must not be forgotten that the results we obtain are very rarely of immediate practical value, and that as a rule *we* reap no pecuniary advantage. I venture to think, in fact, that it is remarkable that so much, not that so little, is done, and that reproach rests very lightly upon the profession in this matter. Whether our national pride will prevent our being much longer beholden to foreigners for by far the greater number of new facts in chemistry is a difficult question to answer, and must rest with the public!

The occasions on which we teachers of science subjects are able to bear witness in public are of necessity few. Deeply sensible, not only of the honour, but also of the responsibility of my position as President of this Section, I felt that it was my duty to avail myself of this opportunity. Being a teacher who is interested in teaching; being convinced of the existence of most serious faults in our educational system; feeling that the present is a most critical period: I have not hesitated to speak very freely. Some of the difficulties to which I have referred might soon disappear if science teachers generally would agree to consider them together, and I believe that it would be a very great advantage if an association for the discussion of educational questions were formed of the staffs of our science colleges throughout the country. The special difficulties which surround our science colleges, and prevent them from exercising their full share of influence upon the advancement of our national prosperity might also be removed at no distant date; but I see only one way of accomplishing this, and I fear it will hardly find favour: it is by their all becoming vested in the State. In this country we like to do things in our own way, and the objection will at once be raised that this would deprive all the colleges of their individuality, and would tend to crush originality and to stereotype teaching. If I thought so, I should never make the suggestion. But it would not, provided that complete academic freedom were secured to the staff, and each college were left to adjust itself to local requirements; efficiency would be maintained by the competition of the various colleges. Local enterprise, which has hitherto been trusted to, is clearly breaking down under the tremendous strain of modern educational requirements: some change must ere long be made.

I now pass to the consideration of a subject of special interest in this Section, which I think requires the immediate earnest attention of chemists and physicists

combined—that of *Chemical Action*. In his Presidential Address to the Association last year, Professor Lord Rayleigh made only a brief reference to chemistry, but many of us must have felt that his few remarks were pregnant with meaning, especially his reference to the importance of the principle of the dissipation of energy in relation to chemical change. A year's reflection has led me to think them of peculiar weightiness and full of prophecy. I would especially draw attention to the closing paragraph of this portion of his address: 'From the further study of electrolysis we may expect to gain improved views as to the nature of the chemical reactions, and of the forces concerned in bringing them about. I am not qualified—I wish I were—to speak to you on recent progress in general chemistry. Perhaps my feelings towards a first love may blind me, but I cannot help thinking that the next great advance, of which we have already some foreshadowing, will come on this side. And if I might, without presumption, venture a word of recommendation, it would be in favour of a more minute study of the simpler chemical phenomena.'

Chemical action may be defined as being any action of which the consequence is an alteration in molecular constitution or composition; the action may concern molecules which are of only one kind—cases of mere decomposition, of isomeric change and of polymerisation; or it may take place between dissimilar molecules—cases of combination and of interchange. Hitherto it appears to have been commonly assumed and almost universally taught *by chemists* that action takes place directly between A and B, producing AB, or between AB and CD, producing AC and BD, for example. This, at all events, is the impression which the ordinary average student gains. Our text-books do not, in fact, as a rule, deign to notice observations of such fundamental importance as those of De La Rive on the behaviour of nearly pure zinc with dilute sulphuric acid, or the later ones of Faraday ('Exp. Researches,' Series vii., 1834, 863 *et seq.*) on the insolubility of amalgamated zinc in this acid. Belief in the equation $Zn + H_2SO_4 = H_2 + ZnSO_4$ hence becomes a part of the chemist's creed, and it is generally interpreted to mean that zinc *will* dissolve in sulphuric acid, forming zinc sulphate, not, as should be the case, that *when* zinc dissolves in sulphuric acid, zinc sulphate, &c., are produced. In studying the chemistry of carbon compounds, we become acquainted with a large number of instances in which a more or less minute quantity of a substance is capable of inducing change in the body or bodies with which it is associated without apparently itself being altered. The polymerisation of a number of cyanogen compounds and of aldehydes, the 'condensation' of ketonic compounds and the hydrolysis of carbohydrates are cases in point; but so little has been done to ascertain the nature of the influence of the contact-substance, or *catalyst*, as I would term it, the main object in view being the study of the product of the reaction, that the importance of the catalyst is not duly appreciated. Recent discoveries, however—more particularly Mr. H. B. Dixon's invaluable investigation on conditions of chemical change in gases, and the experiments of Mr. Cowper with chlorine and various metals, and of Mr. Baker on the combustion of carbon and phosphorus—must have given a rude shock, from which it can never recover, to the belief in the assumed simplicity of chemical change. The inference which I think may fairly be drawn from Mr. Baker's observations—that *pure* carbon and phosphorus are incombustible in *pure* oxygen—is indeed startling, and his experiments must do much to favour that 'more minute study of the simpler chemical phenomena' so pertinently advocated by Lord Rayleigh.

But if it be a logical conclusion from the cases now known to us, that chemical action is not possible between any two substances other than elementary atoms, and that the presence of a third is necessary, what is the function of the third body—the catalyst, and what must be its character with reference to one or both of the two primary agents? In the discussion which took place at the Chemical Society after the reading of Mr. Baker's paper, I ventured to define chemical action as *reversed electrolysis*, stating that in any case in which chemical action was to take place it was essential that the system operated upon should contain a material of the nature of an electrolyte ('Chem. Soc. Proc.' 1885, p. 40). In short, I believe that the conditions which obtain in any voltaic element are those which must be

fulfilled in every case of chemical action. There is nothing new in this; in fact, it practically was stated by Faraday in 1834 ('Experimental Researches in Electricity,' Series vii. §§ 858, 859[1]); and had due heed been given to Faraday's teachings we should scarcely now be so ignorant as we are of the conditions of chemical change.

The questions—What is Electrolysis? What is an Electrotyte? are all-important to the chemist, if my contention be accepted. Moreover, the consideration of chemical action from this point of view almost of necessity obliges us also to consider what it is that constitutes chemical affinity. I will not presume to offer any opinion on this subject; but I would recall attention to the prominence which so great an authority as Helmholtz gave in the last Faraday Lecture ('Chem. Soc. Trans.,' 1881, 277) to the view held by Faraday, and which is so definitely stated in a passage in his 'Experimental Researches'[2] (Series viii. 918, also 850 and 869).

Helmholtz used the words: 'I think the facts leave no doubt that the very mightiest among the chemical forces are of electric origin. The atoms cling to their electric charges, and opposite electric charges cling to each other; but I do not suppose that other molecular forces are excluded, working directly from atom to atom.' In the passages which immediately follow, this physicist then makes several statements of extreme importance, which directly bear upon the subject I desire to discuss, and which, therefore, I quote.[3]

[1] 'Those bodies which, being interposed between the metals of the voltaic pile, render it active, *are all of them electrolytes,* and it cannot but press upon the attention of everyone engaged in considering this subject, that in those bodies (so essential to the pile) decomposition and the transmission of a current are so intimately connected that one cannot happen without the other. If, then, a voltaic trough have its extremities connected by a body capable of being decomposed, as water, we shall have a continuous current through the apparatus; and whilst it remains in this state we may look at the part where the acid is acting upon the plates and that where the current is acting upon the water as the reciprocals of each other. In both parts we have the two conditions, *inseparable in such bodies as these,* namely, the passing of a current and decomposition; *and this is as true of the cells in the battery as of the water-cell*; for no voltaic battery has as yet been constructed in which the chemical action is only that of combination: *decomposition is always included,* and is, I believe, an essential chemical part.

'But the difference in the two parts of the connected battery—that is, the decomposition or experimental cell and the acting cells—is simply this: in the former we urge the current through, but it, apparently of necessity, is accompanied by decomposition; in the latter we cause decompositions by ordinary chemical actions (*which are, however, themselves electrical*), and, as a consequence, have the electrical current; and as the decomposition dependent upon the current is definite in the former case, so is the current associated with the decomposition also definite in the latter.'

[2] 'All the facts show us that that power commonly called chemical affinity can be communicated to a distance through the metals and certain forms of carbon; that the electric current is only another form of the forces of chemical affinity; that its power is in proportion to the chemical affinities producing it; that when it is deficient in force it may be helped by calling in chemical aid, the want in the former being made up by an equivalent of the latter; that, in other words, *the forces termed chemical affinity and electricity are one and the same.*'

[3] 'Several of our leading chemists have lately begun to distinguish two classes of compounds—viz., molecular aggregates and typical compounds, the latter being united by atomic affinities, the former not. Electrolytes belong to the latter class. If we conclude from the facts that every unit of affinity is charged with one equivalent either of positive or of negative electricity, they can form compounds, being electrically neutral, only if every unit charged positively unites under the influence of a mighty electric attraction with another unit charged negatively. You see that this ought to produce compounds in which every unit of affinity of every atom is connected with one, and only one, other unit of another atom. This, as you will see immediately, is the modern chemical theory of quantivalence, comprising all the saturated compounds. The fact that even elementary substances, with few exceptions, have molecules composed of two atoms makes it probable that even in these cases electric neutralisation is produced by the combination of two atoms, each

The interpretation of Faraday's law of electrolysis, which Helmholtz has brought under the notice of chemists, is of the most definite and far-reaching character. Does it, however, at all events in the form in which he has put it forward, accord sufficiently with the facts as these present themselves to the chemist's mind? All will recognise that the chemical changes effected by a current in a series of electrolytic cells are equivalent to those which take place within the voltaic cells wherein the current is generated; but in neither case is the action of a simple character: in both a variety of chemical changes takes place, the precise character of which is but imperfectly understood, and we are unable to assign numerical values, either in terms of heat or electrical units, to most of the *separate* changes. Moreover, many compounds are not electrolytes, while others which are regarded by the chemist as their analogues are very readily decomposed by a current of low E.M.F., although no great difference is to be observed in their 'heats of formation;' liquid hydrogen chloride on the one hand, and fused silver chloride on the other, may he cited as examples. Again, how are we to interpret on this theory such changes as that involved in the conversion of stannic into stannous chloride? The former, I suppose, is to be regarded as consisting of an atom of quadrivalent tin charged with four units of, say, positive electricity, and of four atoms of univalent chlorine, each carrying a unit charge of negative electricity; on withdrawal of two of the chlorine atoms, the residual $SnCl_2$ will have two free unit charges of positive electricity. We know that when the temperature is sufficiently lowered two such residues unite, forming Sn_2Cl_4, and it is not improbable that crystalline stannous chloride represents a still later stage of condensation. Is this compatible with the theory? That cases of this kind are contemplated would appear from the reference to 'unsaturated compounds with an even number of unconnected units of affinity,' which we are told may be charged with equal equivalents of opposite electricity; and also from the allusion to the existence of molecules of elementary substances composed of two atoms. It is more than probable that these anomalies would disappear on fuller statement of his views by the author of the theory: I have ventured to call attention to them in the hope of eliciting such statement.

Helmholtz tells us that electrolytes belong to the class of typical compounds, the constituents of which are united by 'atomic affinities,' not to the class of

charged with its full electric equivalent, not by neutralisation of every single unit of affinity. Unsaturated compounds with an even number of unconnected units of affinity offer no objection to such an hypothesis: they may be charged with equal equivalents of opposite electricity. Unsaturated compounds with one unconnected unit, existing only at high temperatures, may be explained as dissociated by intense molecular motion of heat, in spite of their electric attractions But there remains one single instance of a compound which, according to the law of Avogadro, must be considered as unsaturated even at the lowest temperature—namely, nitric oxide (NO), a substance offering several very uncommon peculiarities, the behaviour of which will be perhaps explained by future researches.' The popular mistake is here made of assuming that elementary substances, with few exceptions, have molecules composed of two atoms. We now know considerably over seventy elements, but of these the molecular weights in the *gaseous* state of only thirteen have been satisfactorily determined. The gaseous elements hydrogen, oxygen, nitrogen and chlorine, and also bromine, iodine and tellurium, have diatomic molecules; phosphorus and arsenic have tetratomic molecules; those of sulphur are hexatomic, and selenium molecules are probably of similar constitution, but more readily broken down than those of sulphur; lastly, cadmium and mercury molecules are monatomic. It is more than probable that carbon, and also silicon and boron form highly complex molecules. Of the remaining undetermined elements, the greater number are metals, and it is not unreasonable to assume that many of these will be found to resemble cadmium and mercury in molecular composition. It is clear, however, that at present we have no right to say that the elementary molecules are, as a rule, diatomic. It would assist in removing this error if chemists would consistently place *after* the symbol the numeral indicating the 'atomicity' of the elementary molecule—thus, Hg_1, Cd_1, O_2; and if in all cases when a numeral is absent, or is placed *before* the symbol, it were understood that advisedly no indication of the molecular state is afforded.

'molecular aggregates.' Is this the fact? Before chemists can accept this conclusion many difficulties must be removed which appear to surround the question. In the first place, it is in the highest degree remarkable that, with the one single exception of *liquefied* ammonia, *no known binary hydride is in the liquid state an electrolyte*: liquid hydrogen chloride, bromide and iodide, for example, withstanding an E.M.F. of over 8,000 volts (8,040 De La Rue cells: Bleekrode). Water, again, according to Kohlrausch's most recent determinations, has an almost infinite resistance. Yet a mixture of hydrogen chloride and water readily conducts, and is electrolysed; an aqueous solution of sulphuric acid behaves similarly, although the acid itself has a very high resistance.[1] Very many similar examples might be quoted, but it is well known that aqueous solutions generally conduct more or less perfectly, and are electrolysed.[2]

The current belief among physicists would appear to be that the dissolved electrolyte—the acid or the salt—is almost exclusively primarily decomposed (Wiedemann, 'Elektricität,' 1883, ii. 924). We are commonly told that sulphuric acid is added to water to *make it conduct*, but the chemist desires to know why the solution becomes conducting. It may be that in all cases the 'typical compound' is the actual electrolyte—*i.e.* the body decomposed by the electric current—*but the action only takes place when the typical compounds are conjoined and form the molecular aggregate*, for it is an undoubted fact that HCl and H_2SO_4 dissolve in water, forming 'hydrates.' This production of an 'electrolytical system' from dielectrics is, I venture to think, *the* important question for chemists to consider. I do not believe that we shall be able to state the exact conditions under which chemical change will take place until a satisfactory solution has been found.

F. Kohlrausch ('Pogg. Ann.' 1876, 159, 233) has shown that, on adding sulphuric acid to water, the electric conductivity increases very rapidly until when about 30 per cent. of acid is present a maximum (6,914) is attained; conductivity then diminishes almost as rapidly, and a minimum (913) is reached when the concentration corresponds with that of a monohydrate (H_2SO_4,OH_2); from this point conductivity increases somewhat (to 1,031 at 92·1 per cent. H_2SO_4), and then again falls, and is probably zero for the pure acid; on adding sulphuric anhydride to the acid conductivity again increases. Solutions of other acids and of a number of salts—chiefly deliquescent and very soluble salts—also exhibit maximum conductivity at particular degrees of concentration. In no other case has the existence of two maxima, such as are observed in solutions of sulphuric acid, been established; but probably this is because the experiments either have not been, or cannot well be, carried out with pure substances or very concentrated solutions. Solutions of less soluble salts increase in conductivity as the amount of salt dissolved increases.

Kohlrausch has suggested, as an explanation of the influence of the 'solvent' on the conductivity of an 'electrolyte,' that in a solution the ions which are being transferred electrolytically come less frequently into collision than would be the case in the pure substance. There is therefore less opportunity for the formation of new molecules, and the ions are able to travel farther before entering into combination.

Regarding the question from a chemist's point of view, however, I cannot help thinking that this explanation is scarcely satisfactory or sufficient; and I cannot

[1] It is more than probable that the most nearly pure sulphuric acid which can be obtained is not homogeneous, but is at least a mixture of H_2SO_4,$H_2S_2O_7$ and 'hydrated compounds' in proportions depending on the temperature, and hence that (pure) sulphuric acid, H_2SO_4, like water, would behave as a dielectric.

[2] On the other hand, it is remarkable that, whereas liquified ammonia may be electrolysed, an aqueous solution of ammonia is a most imperfect conductor (Faraday, F. Kohlrausch), although solutions of ammonium salts compare favourably in conductivity with corresponding sodium and potassium salts. This fact serves *somewhat* to allay the suspicion that Bleekrode did not take sufficient precautions to dry the ammonia; but his result cannot, I think, be accepted as final, on account of the relatively high E.M.F. required, and the repetition of the experiment with every precaution to ensure purity of the gas is most important. Faraday regarded the decomposition of ammonia on electrolysis of its solution as merely the result of secondary action.

resist the feeling that the production of electrolytically conducting solutions from dielectrics is in some manner dependent upon the occurrence of chemical change. If the composition of the solutions of maximum conductivity be calculated,[1] it will be seen that they contain but a limited number of water molecules; thus the solution of sulphuric acid of maximum conductivity (at 18°) contains 30·4 per cent. of acid, and therefore has the composition $H_2SO_4 : 12·4\ H_2O$ (approximately); for nitric acid the ratio is 1 : 8; for acetic acid it is about 1 : 17. Now, it is highly remarkable that the solutions of maximum electric conductivity are also very nearly those in the formation of which nearly the maximum amount of heat is developed; this will at once be obvious on comparison of the curves given by Thomsen ('Thermochemische Untersuchungen' vol. iii.), and by Kohlrausch. In the chemist's experience, the point of maximum heat development is usually near to the point of maximum chemical change, and I think, therefore, that we are justified in concluding that, even if electrical conductivity be not a maximum at a particular concentration on account of the presence of a particular hydrate (belonging to the class of molecular aggregates) in maximum amount, at all events the 'structure' of the system is especially favourable, and the 'chemical influence' exerted by the one set of molecules upon the other is at a maximum at the point of maximum conductivity. The fact that the amount of sulphuric acid required to form a solution of maximum conductivity increases with temperature—

Temp.	0°	10°	20°	30°	40°	50°	60°	70°
Per cent.	30·2	30·9	31·7	32·5	33·5	34·1	34·5	35·4

and also the fact that the maxima and minima of conductivity tend to become obliterated with rise of temperature (Kohlrausch), are both in accordance with the view that conductivity is in some way dependent upon chemical composition, as the effect of rise of temperature would be to cause the dissociation of hydrates such as I have referred to. The increase in conductivity of aqueous solutions with rise of temperature would appear to be against the view here put forward; but it is probable that this may be largely due to diminution in viscosity and increase in the rate of diffusion.

Our knowledge of the binary metallic compounds, which are generally admitted to be electrolytes *per se*, also affords evidence, I think, of an intimate relation between chemical constitution and 'electrolysability.' It has been pointed out (comp. L. Meyer, 'Theorien d. mod. Chemie,' 4th ed. p. 554) that, whereas all the metallic chlorides and analogous compounds which cannot be electrolysed are easily-volatile bodies, the electrolysable metallic chlorides, &c., are fusible only at high temperatures. A careful discussion of the various known cases does not, however, justify the conclusion that decomposition takes place, or not, according as the temperature at which the body assumes the liquid state—and at which, therefore, there is full opportunity given for electrolysis to take place—is high or low, especially as recent observations show that electrolysis may take place prior to fusion. But it is especially noteworthy that many of the chlorides, &c. which are electrolytes undoubtedly contain more than a single atom of metal in their molecules; indeed, after careful consideration of the evidence, I am inclined to go so far as to put forward the hypothesis *that among metallic compounds only those are electrolytes which contain more than a single atom of metal in their molecules.* No difficulty

[1] Formula	Formula weight	Percentage in solution of max. cond.	Composition in approximate mol. ratios	Conductivity
HNO_3	63	29·7	1 : 8	7330
HCl	36·4	18·3	1 : 9	7174
H_2SO_4	98	30·4	1 : 12·4	6914
H_3PO_4	98	46·8	1 : 6	1962
$C_2H_4O_2$	60	16·6	1 : 17	15·2
KOH	56	28·1	1 : 8	5995
NaOH	40	15·2	1 : 12·7	3276

will be felt in granting this of cuprous and stannous chlorides, and even of cadmium, lead, silver and zinc chlorides; but opinions will differ as regards the metals of the alkalies and alkaline earths.[1] Assuming the constitution of metallic electrolytes to be such as I have suggested, it is not improbable that on electrolysis a part only of the metal is determined to the one pole, the remainder being transferred along with the negative radical to the opposite pole. Hittorf, indeed, has already put forward this view in explanation of the remarkable results he obtained on determining the extent of transfer of the ions in aqueous and alcoholic solutions of the chloride and iodide of cadmium and zinc.

Again, an argument in favour of a connexion between chemical constitution and electrical conductivity is the fact that carbon, sulphur, selenium and *phosphorus* each exist in conducting and non-conducting modifications, as it can scarcely be doubted that the so-called allotropic modifications of these elements are differently constituted.

It appears, as I have already said, to be the current belief that when aqueous solutions are submitted to electrolysis, as a rule, the dissolved substance, and not the water, is the actual electrolyte. Without reference to the question I have raised as to the constitution of an electrolyte, it appears at least doubtful whether this view can be justified by appeal to known facts; at all events, I have failed to find satisfactory evidence that such is the case. Moreover, as sulphuric anhydride dissolves in water with considerable development of heat, it would appear that more work has to be done to separate hydrogen from sulphuric acid than to separate it from water; on this account we might expect that the water rather than the acid would be decomposed. Are not perhaps both affected according to the proportions in which they are present? The marked variation in the extent to which the negative ion is transferred to the positive pole, as observed by Hittorf, when solutions of different degrees of concentration are electrolysed, would appear to support this view. The difference in the products, according as dilute or very concentrated solutions of sulphuric acid are used, may also be cited as an argument that the chemical changes effected vary with the concentration; but, on the other hand, it is quite possible that the observed differences may result from the occurrence of purely secondary changes. Ostwald has recently put forward the view that one *or more* of the hydrogen atoms of certain acids are split off according to the concentration of the solution.

I call attention to this because I conceive that it has a most important bearing on the discussion of the nature of the chemical changes which occur during the dissolution of metals. Formerly it was said that, when zinc acts upon dilute sulphuric acid, the zinc displaces the hydrogen of the water and the resulting zinc oxide dissolves in the acid, forming zinc sulphate; the modern explanation advocated by most chemists has been that the metal directly displaces the hydrogen of the acid: in fact, that this is the nature of the change whenever an acid is acted upon by a metal. If in a solution of sulphuric acid, of whatever strength, the acid be the actual electrolyte, I imagine that we are right in accepting this modern view; but if the water be the electrolyte, we must, to be consistent, return to the view that the oxide—more probably in most cases the hydroxide—is the primary product. And if it can be

[1] We may regard as evidence in support of this explanation the fact that neither beryllium chloride, which fuses at 600°, nor mercuric chloride, is an electrolyte, as both of these, at temperatures not far removed from their boiling-points, exhibit the simplest possible molecular composition. It should be pointed out, however, that Nilson and Patterson found it possible to determine the density of beryllium chloride gas at a temperature 100°–150° below the melting-point found by Carnelly; but they were not able to say that fusion took place. Clarke's recent interesting observations on mercuric chloride and iodide do not, I think, suffice to prove that these compounds are electrolytes; it is more than probable that electrolysis is preceded by the formation of mercurous compounds. Even an aqueous solution of mercuric chloride does not conduct appreciably better than water (Buff). I should perhaps add that the mere presence of more than a single atom of metal in the molecule does not, I believe, alone constitute the compound an electrolyte; much depends probably both on the nature of the metal and on the structure of the molecule.

shown that during electrolysis both water and acid, according to circumstances—concentration, E. M. F., &c.—undergo change, it will be necessary to teach that in a similar manner the action of metals on acids is no less complex. Our views on the action of metals on concentrated sulphuric acid and on solutions of nitric acid of various strength must also materially depend on the interpretation of the behaviour of these acids on electrolysis with varying electromotive forces.

Having thus fully explained why I venture to think that Helmholtz's definition that 'electrolytes belong to the class of typical compounds, not to that of molecular aggregates,' is somewhat open to question, it now becomes necessary to make some slight reference to the constitution of these so-called molecular aggregates. Although opinions differ widely as to the definition to be given of a typical or atomic compound, and of a molecular compound or aggregate, the majority of chemists appear to agree that we must recognise the existence of two distinct classes of compounds. Professor Williamson, in his address to this Section at the York meeting (1881), entered at length into the discussion of this question, and in very forcible terms objected to the recognition of molecular combination as something different from atomic combinations; in this I, in the main, agree most fully with him. He further said that he had been led to doubt whether we have any grounds for assigning any limits whatever to atomic values, and he adduced a number of cases which, in his opinion, afforded illustration of a capability of elements to assume greater atomic values by combining with both negative and positive atoms than with atoms of one kind only; for example, he cited the compounds K_2CuCl_4 and K_2HgCl_4 as proof that copper and mercury may assume hexad functions; the compound K_2AgI_3 as an illustration that silver may act as a pentad; and the compounds $KAsF_6$ and K_2AsF_7 were regarded by him as evidence of the heptadicity and nonadicity of arsenic.

I have long been of opinion that the experimental investigation of this question is of great importance, and I believe that it must ere long attract the attention it deserves. The problem will be solved, not by discussions on the fertile theme of valency, but by determining the structure—the constitution—of bodies such as were referred to by Professor Williamson.

My own view on the question is a very decided one. So far as the mere definition of valency is concerned, I entirely agree with Lossen; and, as I have said, I hold with Prof. Williamson that in all compounds the constituents are held together by atomic affinities, and atomic affinities only, but I believe that the formation of so-called molecular compounds is mainly due to peculiarities inherent more especially in the negative elements—*i.e.*, the non-metals and metalloids, and not in the positive elements—the metals; in other words, to the fact that, as was first pointed out, I believe, by Lothar Meyer, the negative elements tend to exhibit a higher valency towards each other than towards positive elements. The view I take, then, is, that in the majority of so-called molecular compounds the parent molecules are preserved intact in the sense in which a hydrocarbon radical, such as ethyl, is preserved intact in an ethyl compound, being held together by the 'surplus affinity' of the negative elements. Thus I would represent the compounds K_2CuCl_4 and K_2HgCl_4 as containing copper and mercury of the same valency as the metal in the parent chloride, and regard them as compounds of the radicals $(CuCl_2)$, $(HgCl_2)$ and (KCl); a view which may be expressed by the formulæ

$$Cu\begin{matrix}Cl\,.\,ClK\\Cl\,.\,ClK\end{matrix}\qquad Hg\begin{matrix}Cl\,.\,ClK\\Cl\,.\,ClK\end{matrix}$$

The arsenic compounds referred to may be similarly represented

$$F_4AsF\,.\,FK\qquad F_3As\begin{matrix}F\,.\,FK\\F\,.\,FK\end{matrix}$$

We do not hesitate to attribute to the so-called double cyanides this order of structure, without in any way supposing that the metal changes in valency. Evidence that the 'constituent radicals exist unchanged in molecular compounds' is afforded by facts such as that ferrous and potassium chlorides, for example, form a compound which obviously is still ferrous, being of a green colour, which would

hardly be the case if the valency of the iron were increased; and that in like manner the compounds formed from stannous chloride manifest all the properties of stannous derivatives.

Whatever be the nature of chemical affinity, it is difficult to resist the conclusion that the 'charge' of a negative radical especially is rarely, if ever, given up all at once; that its affinity is at once exhausted. It would also appear that the amount of residual charge—of surplus affinity—possessed by a radical after combination with others depends both on its own nature and that of the radical or radicals with which it becomes associated. Differences such as are observed in the composition and stability of the hydrates of the salts of an acid—the sulphates, for example—clearly point to this. Other illustrations are afforded by the manner in which chlorhydric acid yields chlorhydrates of some metals and chlorides of others.[1]

It is noteworthy, however, that often those elements which from the ordinary point of view are regarded as possessed of feeble affinities are those which manifest the greatest tendency to form molecular compounds. Thus, it is commonly held that, of the three elements, chlorine, bromine and iodine, chlorine has the highest and iodine the lowest affinity, and this view accords well with the recent observations of V. Meyer on the relative stability of their diatomic molecules at high temperatures; but nevertheless we find that the compound which HI forms with PH_3 is far more stable than that of HBr or HCl with this gas; and it is well known that mercuric *iodide* has a much greater affinity for other iodides than have mercuric bromide and chloride for the corresponding bromides and chlorides.[2]

The recognition of the peculiarity in the negative elements to which I would attribute the formation of molecular compounds must, I think, exercise an important influence in stimulating and directing the investigation of these compounds and of compounds other than those of carbon; in the near future the determination of the structure of such compounds should occupy an important share of the chemist's attention. It will perhaps afford a clue in not a few cases which are not altogether satisfactorily interpreted in accordance with the popular view of valency. I may instance the formation of (?) polymeric metaphosphates, of complex series of silicates and tungstates, and of compounds of hydrocarbons with trinitrophenol. It may even serve to explain some of the peculiarities of the more complex carbohydrates.

It is one of the most clearly established of the 'laws of substitution' in carbon compounds that negative radicals tend to accumulate: numerous instances are afforded by the behaviour of paraffinoid compounds with chlorine, bromine and oxidising agents, and by that of unsaturated paraffinoid compounds when combining with hydrogen bromide and iodide. The special affinity of negative elements for negative is not improbably the cause of this accumulation. A similar explanation may perhaps be given of some of the peculiarities which are manifested by benzenoid compounds.

I would even venture to suggest that in electrolysing solutions the friction arising from the attraction of the ions for each other is perhaps diminished, not by

[1] The name chlorhydric acid is here applied to the compound $HCl(OH_2)_x$—probably $x=1$—which, according to Thomsen, is present in an aqueous solution of hydrogen chloride. It would be an advantage if we ceased to speak of HF, HCl, HBr, HI, as acids, and always termed them hydrogen fluoride, chloride, bromide and iodide respectively. The names hydric chloride, bromide, &c., might with equal advantage be altogether abandoned; hydrochloric acid is objectionable, as suggesting a relation to chloric acid. The names fluor-, chlor-, brom- and iodhydric, as applied to the *acids* present in aqueous solutions of the hydrides, are especially appropriate as indicating that they are compounds containing the radical water—that they are hydrates: indeed, it would be well to restrict the use of hydric and hydro- to bodies of this kind, and to speak of hydrides as hydri-, not as hydro-, derivatives. It would then be possible to give comparatively simple names even to complex hydrates.

[2] Thomsen gives the values in heat units as—

$$\begin{aligned} HgCl_2,2KClAq &= -1380 \\ HgBr_2,2KBrAq &= 1640 \\ HgI_2,2KIAq &= 3450 \\ HgCy_2,2KCyAq &= 8830 \end{aligned}$$

the mere mechanical interposition of the *neutral* molecules of the solvent—in the manner suggested by Kohlrausch—but by the actual attraction exercised by these molecules upon the negative ion in virtue of the affinities of the negative radicals.

One result of increased attention being paid to the investigation of problems such as I have indicated will probably be that we shall be called upon to abandon some even of our most cherished notions. I would suggest, for example, that it may become necessary to regard nitrogen peroxide not as a mixed anhydride of nitrous and nitric acids, but as a compound of two NO_2 groups; its conversion into nitrite and nitrate affords no proof of its constitution, as chlorine peroxide, ClO_2, which exhibits no tendency whatever to combine with itself, also yields both chlorite and chlorate. A greater shock may result from a conviction arising that not only carbon dioxide, but sulphur dioxide, and perhaps even sulphur trioxide, dissolve in water, forming *hydrates*—$SO_2{\cdot}OH_2$, $SO_3{\cdot}OH_2$—not *hydroxides*. In recent times, in discussing questions of this kind we have perhaps often been led to attach too much importance to the argument from analogy; it is not improbable that, especially in the case of compounds other than those of carbon, chemical change involves change in structure more frequently than we are apt to believe.

It is possible that a precise estimate of what, for want of a better name, I have spoken of as residual affinity, may sooner or later be obtained, if the view Professor Lodge has propounded in his paper 'On the Seat of the Electromotive Forces in a Voltaic Cell' be correct, that the cause of the volta effect is the *tendency to chemical action* between the bodies in contact; that, for example, chemical strain at the air-contacts is the real cause of the apparent contact-force at the junction of two metals in air. Professor Lodge, if I understand his argument, appears to assume that the air effects are in some way dependent on the presence of 'dissociated oxygen atoms.' I think this is probably an entirely unnecessary assumption; of late years, no doubt, it has been the fashion to attribute the occurrence of changes of various kinds to the presence of products of dissociation, but probably to a very unnecessary extent. Recent investigations to which I have alluded show that there are other factors of extreme importance: for example, that water must be present in order to render a mixture of carbonic oxide and oxygen explosive. Again, the observations of V. Meyer and Langer have shown that, whereas chlorine *violently attacks* platinum at low temperatures, it is *without action* upon it at temperatures between about 300° and 1,300°, but then *again begins to act* upon it, the action becoming violent at 1,600° to 1,700°. I have little doubt that the action at low temperatures is dependent upon the presence of moisture; if it were due to dissociated chlorine atoms, the action should increase with rise of temperature without break. In short, I see no reason to assume that oxygen at ordinary temperatures consists of other than diatomic molecules.[1] Assuming Professor Lodge's view to be correct, the strain exists in virtue of the attraction which the oxygen molecules exert upon the metal molecules. On this assumption, I can well understand that the method of calculation followed by Professor Lodge will not uniformly lead to satisfactory results. The 'heat of combination' is not necessarily a measure of 'affinity.' The values are in all cases algebraic sums of a series of values, scarcely one of which is known, and, as I have already pointed out, the affinities of the molecules are by no means always of the same order as the affinities of the constituent atoms: for example, in all probability, oxygen-stuff has a higher absolute affinity than sulphur-stuff; chlorine-stuff a higher absolute affinity than iodine-stuff, yet iodine and sulphur compounds, more often than not, seem to exhibit more residual affinity than chlorine and oxygen compounds. So that, from Professor Lodge's point of view, chlorine would have the higher and iodine the lower contact values; whereas, from my point of view the reverse might often be the case. I point this out because it appears to me that we here have an opportunity of testing the question experimentally, and seeing that it is possible practically to prevent chlorine from attacking metals by excluding moisture, I do not take the hopeless

[1] This conclusion would also lead me to disbelieve entirely in the explanation which Clausius has given of electrolysis.

view that Professor Lodge and others seem to hold regarding the possibility of settling the important question of pure contact *versus* chemical action by appeal to experiment. I may also point out that according to my hypothesis it is possible that the metals may exert a considerable attraction for each other, especially those having monatomic molecules:[1] many alloys are undoubtedly compounds; possibly not a few are compounds of the 'molecular aggregate' class.[2]

To return now for but a few moments to the subject of chemical change and its intimate connexion with electrical phenomena. One application I would make of the views here put forward would be to explain the superior activity of bodies in the *nascent state*, and in particular of nascent-hydrogen. Briefly stated, I believe it to consist in the fact that nascent hydrogen is hydrogen in circuit—hydrogen in electrical contact with the substance to be acted upon. The experiments of Faraday and of Grove afford the clearest evidence that in order to bring about action between hydrogen and oxygen at ordinary temperatures it is merely necessary to make them elements in a voltaic circuit. The difference in the effects produced by 'nascent hydrogen' from different sources is, I imagine, attributable to the variations in E.M.F. which necessarily attend variations in the constituent elements of the circuit.

It is not so easy, however, as yet to explain some of the changes which take place at high temperatures. Mr. Dixon's experiments have proved that a mixture of carbonic oxide and oxygen is non-explosive, but that explosion takes place if water be present, the velocity of the explosive-wave depending upon the amount of water present. When the mixture of the two gases is 'sparked,' change takes place, but only in the path of the discharge. Mr. Dixon considers 'that the carbonic oxide becomes oxidised at the expense of the water, the hydrogen *set free* then becoming reoxidised.' M. Traube, who in a series of papers has called attention to the importance of water in promoting oxidation, has suggested that the oxygen and carbonic oxide together act on the water, forming hydrogen peroxide and carbonic acid: $CO + 2OH_2 + O_2 = CO(OH)_2 + H_2O_2$; and that the peroxide then reacts with carbonic oxide to form carbonic acid: $CO + O_2H_2 = CO(OH)_2$. The carbonic acid, of course, is resolved into carbon dioxide and water ('Berichte,' 1885, p. 1890). Traube actually shows that traces of hydrogen peroxide are formed during the combustion. It appears to me that the water may exercise the same kind of action as it (or rather dilute sulphuric acid) exercises in a Grove's gas battery, and that its hydrogen does not become free in any ordinary sense. The produc-

[1] Assuming that the heat absorbed in raising the temperature of a solid is mainly expended in overcoming intermolecular attraction, the high 'atomic heat' of metals may be regarded as evidence that their molecules powerfully attract each other, and hence that their molecular composition is relatively simple; and on this view the 'atomic heat' of carbon and of a number of other non-metals and of some metalloids is low owing to the extent to which the 'affinity' of the atoms is, as it were, exhausted in the formation of their molecules. Comparison of the 'molecular heats' of chlorides and similar compounds with those of the oxides lends much support to this view, as we have reason to believe that the chlorides—which have high 'molecular heats'—are of relatively simple molecular composition, and that the oxides—which have low 'molecular heats'—are of relatively complex molecular composition. The great difference in the specific heat of ice and liquid water may perhaps be similarly explained on the assumption that ice consists of complex aggregates of H_2O molecules, whereas liquid water consists of aggregates of much simpler composition.

[2] The study of alloys from this point of view will probably furnish interesting results. It is noteworthy that the contact difference of potential of brass is less than that of copper, and much less than that of zinc, with the same solution, in all the cases quoted by Ayrton and Perry; thus—

	Zinc	Copper	Brass
Alum	−·536 volt.	−·127	−·014
Sea salt	−·565 „	−·475	−·435
Sal ammoniac	−·637 „	−·596	−·348

It is especially important to examine the copper-tin alloys, which vary in electrical conductivity in so remarkable a manner.

tion of hydrogen peroxide is not improbably due to a secondary simultaneous change.

Unlike a mixture of carbonic oxide and oxygen, a mixture of hydrogen and oxygen is violently explosive. If we assume that in both cases the reacting molecules are electrolysed by the very high E.M.F. employed, and that the atoms then combine, it is difficult to explain the difference in the results. Does it arise from the fact that hydrogen is an altogether peculiar element? Or are we to attribute it to an influence which water itself exercises upon the formation of water from hydrogen and oxygen—as in the Grove gas battery? It is noteworthy that the velocity of the explosive-wave in electrolytic gas, according to Berthelot and Vieille, is a close approximation to the mean velocity of translation of the molecules in the gaseous products of combustion calculated from the formula of Clausius (H. B. Dixon, 'Phil. Trans.,' 1884, p. 636). And this is also true of mixtures of carbonic oxide and oxygen, and of nitrous oxide and oxygen with hydrogen. May we therefore assume, as the velocity corresponds with that of the products, that the water exercises the important office of inducing change throughout the mass, and not that the hydrogen is peculiar? I am tempted here to suggest that perhaps the 'induction' observed by Bunsen and Roscoe in a mixture of chlorine and hydrogen is due to the occurrence of a change in which a something is produced which then promotes reaction between the two gases. I here assume that there would be no action between the pure gases.

If I have allowed myself to flounder in among these difficult questions, it is not because I feel that I am justified in speaking with authority, but in the hope that I may be the 'fool,' and that the 'angels' who are well able to discuss them will be led to do so without delay: for chemists are anxiously awaiting guidance on matters such as I have referred to.

Attention must, however, be directed to the study of electrical phenomena by the recent publications of Arrhenius and of Ostwald ('Journal für praktische Chemie,' 1884, **30**, 93, 225; 1885, **31**, 219, 433), and especially by the statement put forward by the latter that the rate of change under the influence of acids (in hydrolytic changes) is strictly proportional to the electrical conductivities of the acids. There cannot be a doubt that these investigations are of the very highest importance.

I trust that in the discussions which we are to have on molecular weights of liquids and solids, and on electrolysis, there may be a free exchange of opinion on some of the points here raised. My reason for selecting these subjects for discussion in this Section will have been made sufficiently clear, I imagine. Last year, in the Physical Section, the idea assumed shape which had long been latent in the minds of many members of the Association, that it is unadvisable, as a rule, to encourage the reading of abstract papers, which rarely are, or can be, discussed. Two important discussions were *introduced* by Professors Lodge and Schuster. We must all cordially agree with Professor Lodge's remarks on the importance of discussing subjects of general interest at these meetings. It appears to me, however, that even a more important work may often be accomplished if the discussion consist of a series of papers which together form a monograph of the subject. I have endeavoured to carry this idea into practice on the present occasion, and a number of friends have most kindly consented to assist. Unexpected difficulties have arisen, and probably we shall none of us succeed in doing all we might wish. I trust, however, that the Section will approve of this first attempt sufficiently to justify my successors in this chair in adopting a similar course.

I much regret that is impossible for me to attempt any review of recent work in chemistry. Not a few really important discoveries might be chronicled, and the patient industry of many who have toiled long to win results apparently insignificant should have been mentioned with high approval. A few remarks I will crave permission for regarding the general character of the work being done by chemists, and regarding that which has to be done.

Complaints are not unfrequently made in this country that a large proportion of the

published work is of little value, and that chemists are devoting themselves too exclusively to the study of carbon compounds, and especially of synthetical chemistry. We are told that investigation is running too much in a few grooves, and it is said that we are gross worshippers of formulæ. Most of these outbursts are attributable to that pardonable selfishness which consists in assigning a higher value to the particular class of work with which one happens to be engaged or interested in than to any other line of investigation; too frequently they result from want of sympathy with, if not absolute ignorance of, the scope and character of the work complained of. It must not be forgotten that chemical investigation, like other investigation, is to a large extent the work of genius; the rank and file must necessarily follow in the order of their abilities and opportunities: hence it is that we work in grooves. The attention paid to the study of carbon compounds may be more than justified both by reference to the results obtained and to the nature of the work before us: the inorganic kingdom refuses any longer to yield up her secrets—new elements—except after severe compulsion; the organic kingdom—both animal and vegetable—stands ever ready before us: little wonder, then, if problems directly bearing upon life prove the more attractive to the living. The physiologist complains that probably 95 per cent. of the solid matters of living structures are pure unknowns to us, and that the fundamental chemical changes which occur during life are entirely enshrouded in mystery. It is in order that this may no longer be the case that the study of carbon compounds is being so vigorously prosecuted: our weapons—the knowledge of synthetical processes and of chemical function—are now rapidly being sharpened, but we are yet far from ready for the attack. As to the value of the work, I believe that every fact honestly recorded is of value; an infinite number of examples might be quoted to prove this. No unprejudiced reader can but be struck also with the improvement in quality which is manifest in the majority of the investigations now published; at no time was more attention given to the discovery of all the products of the reactions studied, and to the determination of the influence of changes in the conditions. As regards our formulæ, those who look upon the outward visible form without proper knowledge of the facts symbolised, and who take no pains to appreciate the spirit in which they are conceived, are undoubtedly misled by them. The great outcome of the labours of carbon-chemists has been, however, the establishment of the doctrine of structure;[1] that doctrine has received the most powerful support from the investigation of physical properties, and it may almost, without exaggeration, be said to have been rendered visible in Abney and Festing's infrared spectrum photographs. Some of us look forward to the extension of the doctrine of structure not only to compounds generally, but even to the 'elements.' The relationships between these are in so many cases so exactly similar to those which obtain between carbon compounds, which we are persuaded differ merely in structure, that it is almost impossible to avoid such a conclusion, even in the absence of all laboratory evidence.[2]

As the field of view opens out before us, so does the vastness of the work to be accomplished become more and more apparent; and Faraday's words of 1834 may be quoted as even more appropriate than a half-century ago:

'Indeed, it is the great beauty of our science, CHEMISTRY, that advancement in it, whether in a degree great or small, instead of exhausting the subjects of research, opens the doors to further and more abundant knowledge, overflowing with beauty and utility, to those who will be at the easy personal pains of undertaking its experimental investigation.'

[1] I venture here to direct attention to an extension of the acknowledged theory of structure suggested (by myself, I may say) at the close of the discussion of the van't Hoff–La Bel hypothesis of isomerism in Miller's *Chemistry*, vol. iii. 1880 edition, p. 993. The same view was soon afterwards independently put forward by Dr. Perkin.

[2] F. Exner in a recent paper (*Monatshefte für Chemie*, 1885, p. 249) 'On a New Method of Determining the Size of Molecules,' actually put forward an hypothesis as to the structure of elements.

The following Report and Papers were read:—

1. *Report of the Committee appointed for the purpose of investigating by means of Photography the Ultra-Violet Spark Spectra emitted by Metallic Elements and their combinations under varying conditions.* See Reports, p. 276.

2. *On the Non-existence of Gaseous Nitrous Anhydride.*[1] *By* Professor WILLIAM RAMSAY, *Ph.D., and* J. TUDOR CUNDALL.

The existence or non-existence of nitrous anhydride in the state of gas cannot be decided, as attempted by Lunge, by acting on it with any reagent, for that reagent may either decompose it or react with the products of dissociation of nitrous anhydride, NO and $(N_2O_4 + NO_2)$ as if they consisted of the anhydride itself. The only true criterion of the existence or non-existence of such a substance is its vapour density. It was first conclusively proved by the author's experiments that the volume of nitric peroxide when quickly mixed with nitric oxide does not contract, clearly showing that no immediate combination ensues. Dr. Lunge has previously granted the probability of this result, but says that combination is very slow. If the combination of the products of dissociation of a dissociating body is slow, it must equally be the case that the dissociation of the dissociable substance is slow also. If this be so, the vapour density of the gas distilled from liquid nitrous anhydride should have a density 38, corresponding to the formula N_2O_3. A dark blue liquid having been prepared by the usual method, it was fractionated into a large specific gravity balloon by exhausting the balloon and attaching it to the bulb containing the liquid trioxide, certain precautions being taken to ensure that the final pressure was equal to that of the atmosphere. The result was that the first portion had the density of 22·35, while its empirical composition exactly corresponded with the formula N_2O_3. A mixture of $(N_2O_4 + NO_2)$ with NO, in such proportion as to have the composition N_2O_3 should possess, from Professor W. Gibbs' formula, the density 23·42. Supposing the gas thus weighed by us to have contained no N_2O_4 but only $NO + NO_2$, the percentage of N_2O_3 necessary to be added to raise the specific gravity to 22·35 must be 17·63.

On analysis further fractions show a constantly decreasing percentage of nitrogen and a corresponding higher density.

The argument stands thus. On mixing NO and $(N_2O_4 + NO_2)$ no contraction occurs. If combination occurs at all it must occur very slowly. On distilling a liquid containing N_2O_3 the first portion of the distillate has the empirical composition N_2O_3, but is proved by its density to contain at most 17·63 per cent. of N_2O_3, and this on the assumption, known to be false, that no N_2O_4 is present in the gaseous mixture. These facts, combined with Dr. Lunge's statement that the dissociation of nitrous anhydride is uninfluenced by rise of temperature, its behaviour thus being unique, in our opinion decide the point against the existence of gaseous nitrogen trioxide.

3. *On some Actions of a Groves's Gas-battery.* *By* Professor WILLIAM RAMSAY, *Ph.D.*

The ordinary form of gas-battery invented by Groves consists of two tubes containing oxygen and hydrogen respectively, in contact with strips of platinum coated with spongy platinum, which dip into weak sulphuric acid. On connecting the terminals of the platinums outside the liquid a current is set up, and the hydrogen and oxygen combine to form water. But as these gases are not in contact, it must be conceived that at that point where the platinum is in contact with hydrogen and liquid, the water-molecule is decomposed, its oxygen uniting with the gaseous hydrogen to form a new molecule, while the hydrogen is liberated

[1] Published in full, *Jour. Chem. Soc.*, 1885, 672.

from molecule to molecule, until free hydrogen appears at the point of contact of oxygen, platinum, and liquid in the other tube, and unites with oxygen to form again a fresh molecule of water.

Now if indigo-sulphonic acid be present in the acid, it is noticeable after a day or so that the indigo is decolorised when in contact with oxygen, being in all probability converted into isatine, but when in contact with hydrogen no action takes place. The hydrogen therefore does not reduce indigo when it is in the act of combining with oxygen.

If, on the other hand, the conducting liquid be a saturated solution of common salt, and the reacting gases chlorine and hydrogen, the indigo becomes decolorised in both tubes, the bleaching taking place from above downwards. Of course decolorisation takes place at once on admission of chlorine, but it is not until some time has elapsed that reduction by the hydrogen becomes evident. Hydrogen appears therefore to possess the power of reducing indigo when it is in the act of combining with chlorine.

Further experiments were made in order to ascertain whether other substances would comport themselves like indigo. Acid coloured with potassium permanganate was employed, and it was found that in both tubes decolorisation was to be noticed. The decolorisation of permanganate can take place only by reduction, and it must therefore be concluded that on the one hand hydrogen deprived it of its oxygen, and that on the other the action was due either to nascent oxygen, to ozone, or to hydrogen peroxide.

A blank experiment was then made; hydrogen, potassium permanganate, and platinum were left in contact, and it was found that in a few hours the permanganate became colourless. To decolorise permanganate, therefore, does not require the ordinary arrangement of a gas-battery; the feeble currents in the platinised platinum, or possibly the action of occluded hydrogen, are themselves sufficient to cause reduction and the union of the hydrogen.

A similar experiment was made with oxygen, platinum, and permanganate; after thirty-six hours the permanganate had not lost its colour. The couple appears therefore to be necessary to the formation of active oxygen, whether it be in the state of ozone or of hydrogen dioxide.

Experiments were also carried out with a solution of iodine in acidified potassium iodide, with similar results; hydrogen in contact with platinum alone reduced the iodine to hydriodic acid, but oxygen alone had no action. The solution on the oxygen side of the couple was however decolorised, although oxygen in contact with platinum had no action. With ferric chloride also the reaction was in all respects analogous. The results with indigo are therefore the only ones from which a conclusion can be drawn as to the action of the couple. The hydrogen is inactive when the couple consists of hydrogen and oxygen, but active when the couple consists of hydrogen and chlorine. Now to what cause is this difference in behaviour to be ascribed? The gaseous hydrogen is in both cases the same; the production of sodium hypochlorite on the hydrogen side is improbable, inasmuch as the formation of ozone or hydrogen dioxide on the hydrogen side is excluded when the hydrogen-oxygen couple was employed.

I would suggest as a possible explanation of this action that when a molecule of hydrogen reacts with a molecule of chlorine to form hydrogen chloride, atomic hydrogen must exist for a short interval of time. This atomic hydrogen, in the normal state, would at once combine to form molecular hydrogen, but in presence of indigo, indigo-white is produced by the union of the atomic hydrogen with indigo, as is usual when indigo is placed in contact with nascent hydrogen. But on the other hand, when a molecule of oxygen reacts with two molecules of hydrogen to form two molecules of water, it may be possible for the molecule of hydrogen to unite with the oxygen without assuming the atomic or nascent condition, and hence there is no reducing action on the indigo. But the oxygen must assume the nascent or active condition, and it is impossible to say whether its bleaching action on indigo is to be ascribed to direct action or to the formation of such intermediate products as ozone or hydrogen dioxide.

It may perhaps be objected that it is unnecessary to bring in the idea of a

status nascendi in accounting for this action. It is indeed possible that the reaction may be a direct one. Whereas the heat of formation of water is 68,360 cal., that of 2HCl.Aq is 78,640 cal., nearly 10,000 calories in excess; and the reducing action on the indigo may be ascribed to this excess. But with our present views regarding the formulæ of water and hydrogen chloride, which rest so far on a physical proof—that of the volume proportions of the gases and their compounds, it appears to me that the phenomena described present corroborative evidence of a chemical kind of the correctness of the method of writing the equations,

$$H_2 + Cl_2 = HCl + HCl, \text{ and}$$
$$2H_2 + O_2 = H_2O + H_2O.$$

---

4. *On the Spontaneous Polymerisation of Volatile Hydrocarbons at the ordinary atmospheric temperature.*[1] *By* Professor Sir HENRY E. ROSCOE, *F.R.S.*

Some time ago a small quantity of a white crystalline camphor-like substance was sent to me by Mr. W. W. Staveley of West Bromwich, with the information that it had been obtained by him from the most volatile portions of the hydrocarbons, resulting from the decomposition of crude phenol at a red heat. Mr. Staveley writes, 'After standing for some weeks the greater portion of the volatile bodies, boiling from 20° to 30°, was changed by absorption of atmospheric oxygen into bodies boiling between 160° and 170°. After distilling off the lighter portion from the oxidised mixture, the residue in the retort, on cooling, solidified to a white crystalline mass.'

Examination of this product has proved that the above supposition is incorrect, and that the crystalline body is a hydrocarbon having the formula $C_{10}H_{12}$. For the purpose of purification the crude material, which had a yellow colour and was saturated with liquid, was pressed between filter-paper, and afterwards distilled in a vacuum, when it came over without decomposition at about 63° under 9 m.m. of pressure, but is found to decompose when distilled under the ordinary pressure. The hydrocarbon thus purified is perfectly colourless, crystallising in brilliant stellar clusters which melt at 32·9°. It volatilises slowly at the ordinary temperature like camphor, crystals being deposited on the upper part of the vessel containing it. Analysis gave:

	1	2	3	Mean
Carbon	90·78	90·79	90·96	90·84
Hydrogen	9·59	8·69	9·27	9·18
	100·37	99·48	100·23	100·02

The vapour density by Hofmann's method gave:

	1	2
Weight of substance . . .	0·0728 g.	0·1777 g.
Barometer reduced	760·7 m.m.	760·7 m.m.
Mercurial column	686·2 m.m.	587·0 m.m.
Volume of vapour	170·1 c.c.	206·3 c.c.
Temperature of vapour . .	100°	132°
Vapour density	4·39	4·57

The molecular formula $C_{10}H_{12}$ requires a vapour density of 4·57, and the percentage composition C = 90·9 H = 9·10. The sp. gr. of the solid hydrocarbon is 1·012 at 17°·5, the crystals sinking under water in a vacuum. It dissolves readily in petroleum spirit, ether, and alcohol, and possesses a peculiar smell resembling, but distinct from, that of camphor. On exposure to air it rapidly absorbs oxygen and is converted into a yellow resin. When heated in a vacuous tube to 180° for four hours the compound undergoes further polymerisation, and an opaque white battery mass is obtained, the solid portions of which melt with decomposition at 200° to 220°. Both solid and liquid possess a very strong odour. The hydrocarbon $C_{10}H_{12}$ at once combines with bromine, and yields a liquid bromide, which however soon

[1] *Chem. Soc. Trans.* xlvii. 669.

decomposes even in a freezing mixture, and instantly on warming yielding hydrobromic acid and a black resin. Nor could any oxidation product be obtained, the hydrocarbon being apparently completely burnt on treatment with permanganate or chromic acid. Nitric acid dissolves the crystals easily, and the addition of water to the solution throws down an amorphous nitro-compound, but the quantity obtained was insufficient for analysis.

In order to attempt to trace the genesis of this solid hydrocarbon, I had recourse to my friend Mr. Josiah Hardman, who, through his chemist, my former pupil Mr. Irwin, kindly provided me with about 200 litres of the first runnings from 240 tons of tar. This product was carefully distilled, and about 2 litres of liquid boiling below 30° was collected. Of this 200 c.c. was distilled on April 16, the whole boiling below 30°, and leaving no solid residue. On again distilling this portion, which had been at once sealed in a tube nearly filled with the liquid, about 60 c.c. boiled above 30°, and a solid crystalline residue, weighing about two grams, was left behind. This substance melted at 30°, and proved to be the hydrocarbon $C_{10}H_{12}$. One hundred c.c. of another portion of the volatile mixed hydrocarbons, obtained from a second sample of the first runnings, was distilled on March 7. It all came over between 30° and 40°, and no trace of solid crystals was noticeable. On April 13 the liquid contained a high-boiling constituent, and the residue yielded crystals of $C_{10}H_{12}$. On repeating the operation on May 5 the thermometer rose to 75°, and crystals were again obtained from the residue. The fraction of this last portion boiling from 20° to 30° was then sealed up till June 29, when it was again distilled, and from it a small quantity of the crystals was obtained. A third portion of the volatile hydrocarbon from a different tar also exhibited the same behaviour; when first distilled it all came over below 30°, and gave no indication of the presence of the solid hydrocarbon, but after standing in a sealed tube for six weeks the thermometer ran up to 65°, and the last drops of distillate yielded the crystallised substance. Hence there can be no doubt that these volatile hydrocarbons do polymerise spontaneously at the ordinary temperature, and that the solid $C_{10}H_{12}$ is probably the final product.

To identify the volatile hydrocarbon or hydrocarbons which yield the solid substance proved no easy matter. In order to separate the acetylenes the most volatile product obtained was shaken up with an ammoniacal nitrate of silver solution. The light-yellow precipitate obtained consisted mainly of the silver, composed of ethylacetylene, as its molecular weight was found to be 164·3 and 158·7 instead of 161. Portions of the mixture of hydrocarbon thus freed from the acetylene were distilled on March 4, and the whole distilled over at 30°, and showed no trace of crystals. It was then allowed to stand, as described, until April 9, when the liquid was found to yield the same solid body. Hence it appears that hydrocarbons, not acetylenes, are capable of spontaneous polymerisation. For the purpose of separation, these non-acetylene hydrocarbons were brominated. The fraction boiling below 30° yielded a large crop of a well-crystallisable bromine compound which, on analysis, proved to be butine tetrabromide, $C_4H_6Br_4$, the percentage of bromine obtained being 85·7 and 85·3 as against 85·6 required.[1] Amylene dibromide, boiling at 170°–180°, and giving a percentage of 70·0 of bromine as against 69·56, was also obtained in quantity. A liquid pentine tetrabromide, $C_5H_8Br_4$, also occurred amongst the numerous brominated derivatives. This was distilled in a vacuum, and yielded, on analysis, 81·83 per cent. of bromine as against 82·47 per cent. The sp. gr. of this bromide was 2·37. Whether, as seems not unlikely, the new crystalline hydrocarbon is derived from a hydrocarbon, C_5H_6, an isomeride of valylene, must at present remain doubtful, as the search for this body proved unsuccessful.

---

5. *On some new Vanadium Compounds.*[2] *By* J. T. Brierley.

These compounds are formed by the following remarkable reaction:—If a blue solution of hypovanadic sulphate be mixed with a colourless solution of an alkaline

[1] The melting point of this tetrabromide was 116°; that of Helbing's was 99° (*L. Annalen*, 172, 281.)

[2] Printed in full in the *Journal of the Chemical Society*, 1885.

metavanadate, a dark green liquid results, and if to this a slight excess of caustic soda be added, the colour of the solution quickly changes to a deep black. From this dark-coloured solution well-defined crystalline salts can be obtained, having a purple or dark green colour and metallic lustre, in which the condition of oxidation of the metal is intermediate between the tetroxide V_2O_4 and the pentoxide V_2O_5. I have succeeded in preparing five distinct members of this group of salts, viz.:

1. A soluble sodium salt having the composition

$$2V_2O_4 . V_2O_5 . 2Na_2O + 13H_2O.$$

2. A soluble potassium salt

$$2V_2O_4 . V_2O_5 . 2K_2O + 6H_2O.$$

3. An insoluble potassium salt

$$2V_2O_4 . 4V_2O_5\ 5K_2O + H_2O.$$

4. A soluble ammonium salt

$$2V_2O_4 . 2V_2O_5\ (NH_4)_2O + 14H_2O.$$

5. An insoluble ammonium salt

$$2V_2O_4 . 4V_2O_5\ 3(NH_4)_2O + 6H_2O.$$

The soluble potassium and ammonium salts may be converted into the insoluble by boiling the solutions for some time, either alone, or much better with potassium or ammonium acetate, care being taken to keep the boiling liquid slightly alkaline. Free mixed oxides have also been obtained.

FRIDAY, SEPTEMBER 11.

The following Papers were read.—

1. *On the Essential Elements of Plants.* *By* T. Jamieson.

---

2. *The Periodic Law, as illustrated by certain physical properties of Organic Compounds.*[1] *By* Professor Thos. Carnelly, *D.Sc.*

In this paper it was shown that the physical properties of the normal halogen and alkyl compounds of the hydrocarbon radicals exhibit numerous relationships, which, with one exception, are exactly similar to those which have been proved on previous occasions ('Phil. Mag.,' July 1884 and September 1885) to exist between the halogen or the alkyl compounds of the elements.

Hence the general conclusion that the physical properties of the following four classes of compounds (so far as investigated) obey the same rules:—

(1) The halogen compounds of the elements, *i.e.*, of elements with elements.

(2) The alkyl compounds of the elements, } *i.e.*, of elements with hydrocarbon radicals

(3) The halogen compounds of the hydrocarbon radicals, } *i.e.*, of elements with hydrocarbon radicals

(4) The alkyl compounds of the hydrocarbon radicals, *i.e.*, of hydrocarbon radicals with hydrocarbon radicals.

---

3. *Suggestions as to the Cause of the Periodic Law and the Nature of the Chemical Elements.*[2] *By* Professor Thos. Carnelly, *D.Sc.*

The object of this paper was to show that the elements are analogous to the hydrocarbon radicals of organic chemistry, the line of argument being somewhat as follows:—

[1] *Phil. Mag.* January, 1886. [2] *Chemical News.*

As regards physical properties, the alkyl compounds (methides, ethides, propides, &c.) of the elements exhibit exactly the same relationships as the corresponding halogen compounds; hence the alkyl radicals, methyl, ethyl, propyl, &c., have the same function in these compounds as the halogens, chlorine, bromine, and iodine.

Further, the halogen or alkyl compounds of the hydrocarbon radicals exhibit exactly the same relationships as those exhibited by the corresponding compounds of the elements, even when these relationships are of the most minute and intricate kind. The relationships, in the case of both elements and hydrocarbon radicals, and for either their halogen or alkyl compounds, are strictly periodic, the several periods corresponding exactly with the series of elements usually given in tables representing the natural classification of the elements according to the Periodic Law.

It may, therefore, be inferred that the elements are built up of (at least) two primary elements, A and B, which by their combination produce a series of compounds (viz., our present elements) which are analogous to the hydrocarbon radicals.

If the above theory as to the constitution of the elements be true, the Periodic Law would follow as a matter of course, and we should therefore be able to represent the elements by some such general formula as $A_nB_{2nx+(2-x)}$, analogous to that for the hydrocarbon radicals, $C_nH_{2n+(2-x)}$, in which n = the series, and x the group to which the element or hydrocarbon radical belongs.

---

4. *On the Value of the Refraction Goniometer in Chemical work. By* Dr. J. H. Gladstone, *F.R.S.*

The principal points illustrated and enforced in this communication were:

The index of refraction and the length of the spectrum are important physical properties of any substance.

The specific refraction and specific dispersion may be serviceable: 1st, in determining the purity of a substance; 2nd, in the analysis of such mixtures as ethylic and methylic alcohols; 3rd, as a guide in the investigation of organic substances; 4th, as an arbiter between rival theories as to the constitution or structure of particular chemical compounds.

The double or treble refraction equivalents of carbon, oxygen, nitrogen, sulphur, phosphorus, iron, chromium, silicon, &c. offer a specially promising field of research.

---

5. *On the Refraction of Fluorine.*[1] *By* George Gladstone, *F.C.S.*

The author gave data for a more exact determination of the effect of fluorine on the refraction of light than has hitherto been published. A comparison of observations on fluor spar, cryolite, and various artificial compounds containing fluorine, showed that the refraction equivalent of this body must be considerably less than was previously supposed, and that it ranges between 0·3 and 0·8, the mean of the whole being 0·6; and that the specific refraction can, at the highest estimate, be scarcely equal to the half of that of any other substance known.

---

6. *Note on some Conditions of the Development, and of the Activity, of Chlorophyll. By* Professor J. H. Gilbert, *LL.D., F.R.S.*

All who are accustomed to observe vegetation must have been struck with the great variety of shades of green which the foliage of different plants presents. Without pretending to generalise further, it may be stated that, at any rate so far as our common agricultural plants are concerned, they show somewhat characteristic shades of colour, according to the Natural Order to which they belong—the Leguminosæ

[1] Published *in extenso* in the *Phil. Mag.* December, 1885.

differing from the Gramineæ, the Cruciferæ, the Chenopodiaceæ, and so on. But the same description of plant will exhibit very characteristic differences, not only at different stages of growth, but at the same stage in different conditions of luxuriance, as affected by the external conditions of soil, season, manuring, &c., but especially under the influence of different conditions as to manuring.

The Rothamsted Field experiments have afforded ample opportunity for observations of this kind; and it has been quite evident that, in a series of comparable experiments with the same crop, depth of green colour by no means necessarily implied a finally greater amount of carbon assimilation; whilst we have long ago experimentally proved that the deeper colour was associated with relatively high percentage of nitrogen in the dry or solid substance of the herbage; and this obviously means a lower relation of carbon to nitrogen.

Mentioning these facts to Dr. W. J. Russell, who has devoted so much attention to the subject of chlorophyll, he kindly undertook to make comparative determinations of the amounts of chlorophyll in parallel specimens, in which we were to determine the percentages of dry matter and of nitrogen. Accordingly, in June 1882, during the period of active vegetation, Dr. Russell spent a day at Rothamsted for the purpose of collecting appropriate samples, which were taken from several differently manured plots of meadow-grass, wheat, barley and potatoes, respectively.

The following table gives the results of some of these experiments; namely, the percentages of nitrogen, and the relative amounts of chlorophyll, in the separated gramineous and the separated leguminous plants in the mixed herbage of grass land; in specimens of wheat grown by a purely nitrogenous manure, and by the same nitrogenous manure with a full mineral manure in addition; and in specimens of barley grown by a purely nitrogenous manure, and by a mixture of the same

RELATION BETWEEN NITROGEN ACCUMULATION, CHLOROPHYLL FORMATION, AND CARBON ASSIMILATION.

(The figures in parentheses represent determinations in the not fully dried substance).

	Nitrogen per cent. in dry substance	Relative amounts of Chlorophyll	Carbon assimilated per acre per annum	
			Actual	Difference
			lbs.	lbs.
HAY.				
Gramineæ	1·190	0·77		
Leguminosæ	2·478	2·40		
WHEAT.				
Ammonium salts only .	(1·227)	2·00	1,398	– 824
Ammonium salts and mineral manure . . .	(0·566)	1·00	2,222	
BARLEY.				
Ammonium salts only .	(1·474)	3·20	1,403	– 685
Ammonium salts and mineral manure . . .	(0·792)	1·46	2,088	

nitrogenous manure and mineral manure in addition. It is to be borne in mind that the specimens were collected while the plants were still quite green, and actively growing. It should be further explained that the amounts of chlorophyll recorded are, as stated in the table, relative and not actual; that is to say, the figures show the relative amounts for the individual members of each pair of experiments, and not the comparative amounts as between one set of experiments and another.

It will be seen in the first place that the separated leguminous herbage of hay contained a much higher percentage of nitrogen in its dry substance than the

separated gramineous herbage; and that, with the much higher percentage of nitrogen in the leguminous herbage, there was also a much higher proportion of chlorophyll. Under comparable conditions, however, the Leguminosæ eventually maintain a much higher relation of nitrogen to carbon than the Gramineæ, in other words, in their case carbon is not assimilated in so large a proportion to the nitrogen taken up.

Next, it is to be observed that the wheat plants manured with ammonium salts alone show a much higher percentage of nitrogen than those manured with the same amount of ammonium salts, but with mineral manure in addition. The high proportion of chlorophyll again goes with the high nitrogen percentage; but the last column of the table shows that, with the ammonium salts without mineral manure with the high percentage of nitrogen, and the high proportion of chlorophyll, in the dry substance of the green produce, there is eventually a very much less assimilation of carbon. The result is exactly similar in the case of the barley. The plants manured with ammonium salts alone showing the higher percentage of nitrogen, and the higher proportion of chlorophyll, but eventually a much lower assimilation of carbon.

It is evident that the chlorophyll formation has a close connection with the amount of nitrogen assimilated, but that the carbon assimilation is not in proportion to the chlorophyll formed, if there be not a sufficiency of the necessary mineral constituents available. No doubt there had been as much, or more, of both nitrogen assimilated, and chlorophyll formed, over a given area, where the mineral as well as the nitrogenous manure had been applied, the lower proportion of both in the dry matter being due to the greater assimilation of carbon and consequent greater formation of non-nitrogenous substances.

It is of interest to observe, that these results of experiments in the field are perfectly consistent with those obtained by vegetable physiologists in the laboratory; they having found that the presence of certain mineral or ash-constituents, and especially that of potassium, is essential for the assimilation of carbon, no starch being formed in the grains of chlorophyll without the aid of that substance. Sachs says, 'Potassium is as essential for the assimilating activity of chlorophyll as iron for its production.'

7. *A Plea for the Empiric Naming of Organic Compounds. By* Professor ODLING, *F.R.S.*

8. *On the Action of Sodium Alcoholates on Fumaric and Maleic Ethers.*[1] *By* Professor PURDIE, *Ph.D., B.Sc.*

In a previous research ('Chem. Soc. Journ.,' 1881) the author has shown that by the action of sodium alcoholates in alcoholic solution on the ethereal salts of fumaric acid, products are obtained which by saponification yield alkyloxysuccinic acids; thus ethoxysuccinic and butoxysuccinic acids were prepared by the action respectively of a solution of sodium ethylate on ethylic fumarate, and of sodium butylate on butylic fumarate. The object of the present investigation is to elucidate the nature of the chemical reactions concerned in the change, and to compare the etheric acids obtained from fumaric acid with the corresponding additive products procured by similar methods from maleic acid.

Action of sodium methylate on ethylic fumarate.—When a solution of sodium methylate in methylic alcohol is added to ethylic fumarate, the first product of the action is methylic fumarate, which, however, is quickly converted into methylic methoxysuccinate, an oil boiling about 220° C., not without some decomposition. The sodium methylate used converts much more than its molecular proportion of fumaric ether into the addition compound, and it appears that an intermediate compound, a methylic methoxysodosuccinate, is formed, which, however, is continuously decomposed in the presence of alcohol, exchanging

[1] *Jour. Chem. Soc.*, 1885, 855.

its sodium for the hydrogen of the latter while sodium methylate is reproduced. Methoxysuccinic acid procured by decomposition of its calcium salt with sulphuric acid is a crystalline solid melting at 101° to 103° C. Descriptions and analyses of the acid potassium salt and of the calcium and zinc salts are given. The observed conversion of ethylic fumarate into methylic fumarate by the action of sodium methylate is by no means an isolated instance of the interchange of alcoholic radicles between an ethereal salt and an alcohol, but in the instances hitherto observed the interchange is accompanied by partial saponification, as when ethylic oxalate is converted by the action of potassium methylate into potassic methylic oxalate. The author finds that in this reaction normal methylic oxalate is also produced, and that in a similar manner ethylic cinnamate is converted into methylic cinnamate; also, that if the ethylic salt is dissolved in methylic alcohol, the addition of certain salts, such as potassic carbonate, calcic chloride, and ignited borax, induces the interchange of alcoholic radicles.

The general subject of the interchange of alcoholic radicles between ethereal salts and alcohols, induced by various reagents, is being now investigated.

Action of sodium ethylate on ethylic fumarate.—This action has been previously described by the author, and ethoxysuccinic acid and several of its salts characterised. Further observations indicate that here also an intermediate sodium compound is formed, which, however, undergoes partial saponification, forming sodic ethylic ethoxysodosuccinate.

Action of sodium methylate and of sodium ethylate on ethylic maleate.—From the latter reaction no pure products could be obtained, but from the former a methoxysuccinic acid was procured, in its properties closely approximating to, if not identical with, the acid obtained from ethylic fumarate.

Action of sodium methylate on hydric methylic maleate.—As it was found that a solution of maleic anhydride in methylic alcohol could be substituted for the normal maleic ether, this solution was used to obtain the material required for the further examination of the addition products from maleic acid. Hydric methylic maleate is formed by heating maleic anhydrid with methylic alcohol, and the sodic methylic maleate, formed on the addition of sodium methylate, being soluble in the alcohol, is quickly converted into sodic methylic ethoxysodosuccinate, which by saponification yields the sodium salt of a methoxysuccinic acid. The acid, obtained as before from the calcium salt, crystallises in the same manner and has the same melting-point as the corresponding acid obtained from fumaric acid. The salts also which have been already mentioned are identical, with the exception of the zinc salts, which seem to differ slightly. Both salts crystallise with four molecular proportions of water, three of which are given off at 100°, while the remaining molecule is retained to nearly the temperature at which the substance undergoes decomposition; they appear, however, to differ in mode of crystallisation, and the salt derived from fumaric acid loses its last molecule of water of crystallisation at about 205° C., while that obtained from maleic acid does not become anhydrous till about 215° C. The high temperature required for the complete elimination of the water of crystallisation is remarkable, and an exact determination is attended with considerable difficulty, owing to the incipient decomposition of the salts at slightly higher temperatures.

Action of sodium ethylate on hydric ethylic maleate.—By the addition of sodium ethylate to a solution of maleic anhydrid in ethylic alcohol, and subsequent saponification of the product of the reaction, an ethoxysuccinic acid was obtained, the properties of which were found to be identical with those of the corresponding acid from fumaric ether. The calcium and barium salts were analysed and found to agree, as regards water of crystallisation and solubility, with the corresponding ethoxysuccinates previously obtained from fumaric ether.

The above experiments show that fumaric and maleic acids yield alkyloxysuccinic acids, which are identical with one another, or, if not identical, so closely resembling each other that their isomerism must be of the same nature as that of substances which differ only in optical and crystallographic characters. This supposition is by no means improbable in view of the fact that the malic acid prepared from fumaric acid by the action of caustic soda seems to differ from ordinary malic acid and

from Kékulé's inactive malic acid, and in view also of the discovery of Kékulé and Anschütz that fumaric acid on oxidation gives racemic acid, while maleic acid yields mesotartaric acid. On the other hand the slight differences found to exist between the zinc methoxysuccinates—the only difference observed so far between the corresponding addition products—may be due to slight impurity in one or both of the salts, a supposition not improbable, considering that the acids did not give absolutely definite melting-points.

K. Grosner has recently shown (Inaugural Dissertation, Würzburg, 1885), that the ethers of the isomeric pyrocitric acids, when treated with sodium alcoholates, yield alkyloxypyrotartaric acids; he finds, however, that itaconic and mesaconic ethers yield the same acid, and citraconic ether an acid which, though isomeric, is essentially different in its properties from the other. In view of the relation of citraconic to mesaconic acid being in so many respects similar to that subsisting between maleic and fumaric acids, these results are difficult of explanation.

The author intends, as soon as he has a sufficient quantity of material at his disposal, to investigate the optical and crystallographic characters of some of the salts of the ethoxy- or methoxysuccinic acid, obtained from the two parent acids, with the object of determining the identity or isomerism of the acids in question. He purposes also preparing alkyloxysuccionic acids direct from malic acid, so as to compare these acids, obtained from various sources, with each other, and also with the isomeric malic acids now being investigated by Anschütz. He also reserves for further study the intermediate sodium compounds to which reference has been made.

---

9. *On Sulphine Salts derived from Ethylene Sulphide.* *By* Orme Masson, *M.A., D.Sc.*

Ethylene sulphide, as obtained by mixing alcoholic solutions of ethylene bromide and potassium sulphide, is a white amorphous powder, insoluble in any of the ordinary solvents, and very difficult to obtain in a state of purity. When heated to about 160° C., either by itself or with carbon disulphide in sealed tubes, it is converted in great part into the crystalline diethylene disulphide $S{<}\begin{smallmatrix}C_2H_4\\C_2H_4\end{smallmatrix}{>}S$, whose constitution is adduced from its vapour density, its reactions, and from the fact that it is also produced according to the equation

$$C_2H_4{<}\begin{smallmatrix}S\\S\end{smallmatrix}{>}Hg + Br_2C_2H_4 = C_2H_4{<}\begin{smallmatrix}S\\S\end{smallmatrix}{>}C_2H_4 + HgBr_2$$

[Crafts, *Ann. Chem. Pharm.* cxxiv. 110; cxxviii. 220; Husemann, *ibid.* cxxvi. 269.]

The author has found that this crystalline sulphide is capable of combining directly with methyl iodide to form a sulphine salt of the formula

$$S{<}\begin{smallmatrix}C_2H_4\\C_2H_4\end{smallmatrix}{>}S{<}\begin{smallmatrix}CH_3\\I\end{smallmatrix}$$

the combination taking place slowly at the ordinary temperature when the reagents are mixed in ethereal solution, and quickly when they are heated to 60°–70° in sealed tubes.

Diethylenesulphide-methyl-sulphine iodide is freely soluble in hot water, much less so in cold water, practicably insoluble in alcohol or ether. It separates from the hot aqueous solution, on cooling, in opaque white crystals which at first sight appear to be cubical, but are not truly so; and by slow evaporation of the mother liquor it is obtained in the form of transparent prismatic needles. It enters into double decomposition with soluble silver salts, producing well defined crystalline salts of the sulphine radical. Of these the *nitrate* $(C_2H_4)_2S_2(CH_3)NO_3$, and the *sulphate* $\{(C_2H_4)_2S_2CH_3\}_2SO_4 . 3H_2O$, have been examined. From the latter, by the action of barium salts, the chloride and other compounds of the sulphine radical may be prepared. The *chloride* $(C_2H_4)_2S_2CH_3Cl$, yields insoluble or sparingly soluble compounds with certain metallic chlorides. Thus with platinic chloride it gives a heavy yellow precipitate of $(C_2H_4)_2S_2CH_3Cl . PtCl_4$, insoluble in

hot or cold water, alcohol, or dilute acids; and with mercuric chloride it gives a white crystalline compound, $(C_2H_4)_2S_2CH_3Cl.\ HgCl_2$, which is soluble in hot water.

The above-mentioned salts of diethylenesulphide-methyl-sulphine undergo decomposition on heating, and yield sublimates of diethylene disulphide. The haloid salts give also the corresponding methyl compounds. In this behaviour when heated, in their method of formation, and in their general properties, they resemble the salts of trimethyl-sulphine, from which, however, they differ widely in some respects. None of the salts, for instance, are deliquescent, which is a marked property of those of trimethyl-sulphine. The platinic chloride compounds differ in composition and properties. But the most marked characteristic of the diethylenesulphide-methyl-sulphine salts is to be found in their behaviour with alkalis. Thus the sulphate treated with barium hydrate in the cold gives a precipitate of barium sulphate and a solution which is strongly alkaline (before sufficient baryta has been added to decompose all the salt), and from which the sulphate can be again obtained by neutralising with sulphuric acid and evaporating to dryness. This solution undoubtedly contains the base, $(C_2H_4)_2S_2CH_3OH$; which, however, cannot be separated, as it quickly undergoes a change on standing and is converted, by loss of the elements of water, into an oily liquid possessing a very peculiar and disagreeable smell. This oil is produced at once if the iodide or other salt be boiled with potash or even with an alkaline carbonate, which shows that diethylenesulphide-methyl-sulphine hydroxide, unlike trimethyl-sulphine hydroxide, is capable of being turned out of its compounds by the alkalis. The investigation of this oil is not yet completed.

In 1865 Dehn ('Ann. Chem. Pharm. Suppl.,' iv. 83), described the action of ethyl sulphide on ethylene bromide when these are heated together with water in sealed tubes. His main products were ethyl bromide, diethylene disulphide, and triethyl-sulphine bromide; but he also obtained small quantities of two other sulphine compounds. His method was to remove by suitable means the diethylene disulphide and ethyl bromide, to treat the remaining aqueous solution with silver oxide, and then to add excess of hydrochloric acid and fractionally precipitate with platinic chloride. By this means he obtained three distinct compounds, of which the last to come down was the triethyl-sulphine salt, $\{(C_2H_5)_3SCl\}_2PtCl_4$, which is soluble in, and can be crystallised from, hot water. The two others were obtained as yellow precipitates, insoluble in all ordinary solvents. Dehn estimated the platinum in the first of these and the platinum, carbon, and hydrogen in the second. His results led him to conclude that they were compounds of the formulæ $(C_2H_4)_2S^{vi}Cl_2.PtCl_4$ and $(C_2H_4)\ (C_2H_5)_2S^{vi}Cl_2.PtCl_4$,—what he called sulphinic salts, containing hexad sulphur, as opposed to sulphinous salts in which the sulphur is tetrad. It seems almost certain, however, judging from the method of formation, from the properties of the platinic salts themselves, and from the results of Dehn's analyses, that he was really dealing with compounds analogous to the diethylenesulphide-methyl-sulphine platinic-chloride salt described above: viz., with $\{(C_2H_4)_2S_2\}_2(C_2H_4)Cl_2.2PtCl_4$ and $(C_2H_4)_2S_2(C_2H_5)Cl.PtCl_4$. The percentages of carbon, hydrogen, and platinum, calculated from these formulæ, those calculated from Dehn's formulæ, and those found by him, agree with one another within the limits of experimental error; the chlorine and the sulphur, which differ widely, were not estimated by him. If the view here advanced be correct, then Dehn's reaction may be represented by the equations:—

(1) $2C_2H_4Br_2 + 2(C_2H_5)_2S = (C_2H_4)_2S_2 + 4C_2H_5Br.$
(2) $(C_2H_5)_2S + C_2H_5Br = (C_2H_5)_3SBr.$
(3) $(C_2H_4)_2S_2 + C_2H_5Br = (C_2H_4)_2S_2.C_2H_5Br.$
(4) $2(C_2H_4)_2S_2 + C_2H_4Br_2 = \{(C_2H_4)_2S_2\}_2.C_2H_4Br_2.$

10. *An apparently new Hydrocarbon distilled from Japanese Petroleum.* *By* Dr. Divers *and* T. Nakamura.

11. *Description of some new Crystallised Combinations of Copper, Zinc, and Iron Sulphates.* By JOHN SPILLER, *F.C.S.*

It was known that these metallic sulphates were capable of crystallising together, but the author had made experiments with the view of getting definite combinations.

In consequence of the wide differences in the degree of solubility, it was necessary to employ the zinc salt in large excess, so as to force this ingredient into the combination. Sulphate of copper being, on the other hand, much more sparingly soluble, had a tendency to separate out alone, or with at most 8 to 10 per cent. of zinc (or iron) sulphate in admixture.

A large series of well crystallised double salts had been prepared and analysed, of which the following were the most definite examples:—

$$Cu\,Fe\,(SO_4)_2 + 12\ aq.$$
$$Zn\,Fe_3(SO_4)_4 + 28\ aq.$$
$$Zn_2Fe_3(SO_4)_5 + 35\ aq.$$
$$Cu\,Zn_3(SO_4)_4 + 26\ aq.$$
$$Cu\,Zn_4(SO_4)_5 + 33\ aq.$$
$$Cu\,Zn_5(SO_4)_6 + 40\ aq.$$

The last named double salt could be obtained in magnificent pale-blue rhombs, like a tinted calc-spar, but *not* double refracting. The tri-zinc cupric sulphate had long ago been prepared by Lefort, who asserted, however, that it contained 28 molecules of water, a statement which the author believed to be incorrect, finding by his analysis that each salt introduced its own proper amount of water of crystallisation.

SATURDAY, SEPTEMBER 12.

The following Papers were read:—

1. *The Composition of Water by Volume.* By A. SCOTT, *M.A., D.Sc., F.R.S.E.*

No determinations as such of the ratio of the volumes in which oxygen and hydrogen combine to form water have been made since those of Humboldt and Gay-Lussac in 1805. The experiments of Regnault and Amagat show conclusively that neither of these gases obeys Boyle's law, their deviations being in opposite directions; hence if we admit Avogadro's law for perfect gases, it could only be by the merest chance that the true ratio would be 2 of hydrogen to 1 of oxygen. With the improved methods for preparing and measuring gases now at our command, it seemed that this important ratio ought to be redetermined, if possible on a larger scale. The quantities operated on are about 150 c.c. of oxygen and 300 c.c. of hydrogen in each case. Two experiments gave the following ratios—

$$1 : 1{\cdot}994$$

and

$$1 : 1{\cdot}9935$$

or

$$1 : 1{\cdot}9960$$

if the impurity be supposed to exist in oxygen alone.

The purity of the gases was tested by subsequent analysis, of the residue, and ·2 to ·3 c.c. of foreign gas found in 450 c.c. of gas used.

The author, however, hopes by his processes of preparing the gases to obtain them in a still higher degree of purity.

MONDAY, SEPTEMBER 14.

The following Report and Papers were read:—

1. *Report of the Committee on Chemical Nomenclature.*

See Reports, p. 262.

2. *On Electrolysis. By* Professor Oliver J. Lodge, *D.Sc.*

See Reports, p. 723.

3. *On Helmholtz's views on Electrolysis, and on the Electrolysis of Gases. By* Professor Schuster, *F.R.S.*

The author explained some of the views expressed by Helmholtz in his recent papers on electric polarisation and electromotive force, remarking that the President of the Chemical Section had, in his opening address, already drawn attention to the bearing which these views have on chemical theories. The fundamental notion of Helmholtz consists in the assumption of a different attraction of chemical elements for positive and negative electricity. If this is admitted, the difficulties which have been felt in explaining electromotive force of contact disappear. In compound bodies like water, the hydrogen is positively electrified; the oxygen, on the other hand, is charged with negative electricity. If an electromotive force acts on the liquid, the positively charged atom is driven to the negative pole, and the oxygen to the positive pole.

This motion is called forth by any electromotive force, however small, and no work is done except that due to overcoming of the internal resistance. The positively charged hydrogen atom covers the negative electrode, but does not constitute free hydrogen. When the electromotive force is sufficiently strong, an interchange of electricity takes place between the pole and the ion, and then only can the hydrogen separate out.

A large amount of work has to be done to separate the positive charge from the hydrogen. In all decompositions where the elements separate out in a neutral state, it would seem, if these views are correct, that before decomposition an interchange of electricity must take place. Thus, for instance, when aqueous vapour is dissociated by heat, the oxygen must give up its free electricity before it can form neutral oxygen molecules. The conversion of stannic into stannous chloride, mentioned by the President, would have to be accompanied by an interchange of a negative charge on the chlorine with a positive charge on one of the atoms of tin, leaving then both neutral chlorine and neutral stannous chloride.

With respect to the question of rates at which the ions travelled, Professor Schuster thought Professor Lodge had not laid sufficient stress on the remarkable result arrived at by Kohlrausch, that in dilute aqueous solutions, and for a given intensity of current, each element had its own rate of travelling, which was independent of the other ion; thus the barium atom travelled at the same rate whether

originally combined with chlorine or iodine. This result gave a very strong support to the views from which it could be deduced, and proved conclusively the different velocities of different ions.

Finally, Professor Schuster explained his views of the electric discharge of gases, which, in his opinion, presented many analogies to the electrolytic conduction, or rather that called by Helmholtz electric convection. The peculiar phenomena surrounding the negative electrode, as well as stratifications, do not appear in the discharge through mercury vapour, and were probably due to a splitting up of the two-atomed molecules at the negative pole. Phenomena of polarisation consequently appear at the kathode, but the ordinary methods of investigating these phenomena are not available in gases. Experiments which the author hoped to perform in the next few months will decide whether in the gaseous discharge each atom carries off, as in electrolysis, the same quantity of electricity.

---

4. *On the Determination of Chemical Affinity in terms of Electromotive Force. By* C. R. Alder Wright, *D.Sc., F.R.S.*

During the last eight years, the author has carried out (partly by himself, and partly in conjunction with Dr. Rennie and with Mr. C. Thompson), a lengthy series of observations on various points connected with this problem, many of the results of which have been communicated from time to time to the Physical Society of London, and published in its proceedings and in the 'Philosophical Magazine,' in a series of nine memoirs. Whilst these experiments have served to corroborate or correct various previously measured values, and to establish a number of new ones, they have as yet not sufficed to solve the entire problem, but on the contrary, rather tend to indicate that electrical measurements alone are unlikely to give any simple means of readily obtaining exact determinations of the amounts of force and energy involved in the occurrence of chemical changes, at least so far as the more deep-seated phases of these reactions are concerned.

The fundamental idea involved in the conception of the possibility of such determinations being made is due to Sir William Thomson, having been put forth by him in a paper on the Mechanical Theory of Electrolysis.[1] The reasoning involved may be simply stated as follows:—

Faraday has shown (1) that when a compound is electrolysed, the weight of substance decomposed is proportionate to the quantity of electricity passing.[2] In symbols, $n \propto q$, where n is the number of grammes decomposed, and q the quantity of electricity passed. (2) That the weight decomposed by a constant quantity of electricity is proportionate to the chemical equivalent of the substance; *i.e.* if a be the equivalent $n \propto a$. Hence, on the whole, $n \propto aq$; and hence, $n = aq \times$ constant, this constant, or 'Faraday coefficient,' being a numerical value conveniently indicated by the symbol F, just as the Joule value J indicates the somewhat analogous constant relating to mechanical work and heat. Now, suppose the passage of the current to effect no work other than chemical decomposition, and let the lowering of potential (E.M.F.) occurring between the extremities of the mass through which the current passes causing decomposition be e; then eq represents the work done: if f represent the work done by the force of chemical affinity in synthesising a gramme of the compound decomposed from the products of decomposition, the work done is also $nf = aq\text{F}f$; whence $af = \frac{e}{\text{F}}$; that is, the value of the chemical affinity per gramme equivalent of compound is measured by a value in E.M.F.

[1] *Phil. Mag.*, 1851, vol. ii. p. 429,

[2] Various experimenters have been led to believe that under certain conditions, 'conduction without electrolysis' may take place, more especially when extremely feeble currents are passed through acidulated water. The author has shown in a rigorously conducted series of experiments that the non-appearance of products of decomposition in such cases is due to causes other than exceptionality to the law of Faraday (*Phil. Mag.*, April 1881.)

In actual practice the work ultimately done by the passage of a current through an electrolyte is not solely chemical decomposition; a disturbance of the thermal equilibrium also takes place, usually heat evolution. A certain amount of heat evolution, in fact, necessarily ensues, owing to the resistance proper of the medium. In accordance with 'Joule's Law' the work done in this form is C^2Rt (where C is the current, R the resistance proper, and t the time), which may be written $e'q$, since $q = Ct$, and by Ohm's Law CR represents an E.M.F. which may be written e'. If, then, a total fall of potential of E occur, part of this, e', is due to heat evolution through resistance proper; the rest, $E - e'$, is due to other causes, viz. chemical decomposition modified by secondary actions taking place, either spontaneously in the products of electrolysis themselves, or by their causing chemical changes in the electrodes. These secondary actions are usually of such a nature as to cause as final result the production of more or less sensible heat; but generally a greater or less fraction of the energy due to these acts in the same sense as the current itself; that is, the secondary actions assist the current, and cause a less amount of lowering of potential to take place than would otherwise be the case. That portion of the energy due to these secondary changes that thus assists the current may conveniently be spoken of as *adjuvant*, and the rest as *nonadjuvant*.

With certain kinds of electrolytes and electrodes, the amount of adjuvant energy is sufficient not merely to equal the lowering of potential due to the passage of the current *per se*, but to preponderate thereover, so that a *negative* lowering of potential results as the current passes. Such cells constitute ordinary electromotors or 'voltaic circles,' and usually require no external current to start their action.

Whether an electrolytic cell be one in which an actual lowering of potential takes place during the passage of a current from an external source, or one capable of causing an increment in potential of itself without any current passing derived *ab extra*, it is invariably found that the actual potential difference subsisting when a current passes, after correction for the quantity e' due to heat evolution in consequence of resistance proper, is not a constant quantity, but varies with the degree of concentration of the solutions and the nature of the surfaces of the electrodes, and with the density of the current (ratio of current to electrode superficies). With a decomposing cell (where actual lowering of potential takes place) this corrected potential difference increases, *cæteris paribus*, with current density; and with an electromotor (where negative lowering of potential ensues) it decreases therewith; the same rule being observed throughout, that *the greater the density the greater is the amount of nonadjuvant energy due to secondary actions.* In other words, the 'counter E.M.F.' of a decomposing cell, $E - e'$, continually increases with increasing current density, constantly tending towards a limiting value attainable theoretically with an infinite current; whilst the negative counter E.M.F. (or positive E.M.F.) of a voltaic cell or electromotor is at its maximum when the current density is extremely small, and continually decreases as the current density increases.

A large number of experiments have been made (as yet unpublished) with a view of deducing for various electrolytes the limiting values of the 'counter E.M.F.s.' set up during electrolysis, the method adopted being the construction of curves with current densities and counter E.M.F.s as co-ordinates from which empirical exponential equations might be deduced leading to the evaluation of the limiting values for infinite densities. Much labour is necessarily entailed in this class of experiment in order to obtain any results of value even as approximations. The results obtained so far show that these limiting values far exceed those corresponding with the heat evolutions ensuing when the final products of the electrolytic decomposition are made to recombine so as to reproduce the compound experimented with. Thus, for example, the heat disengaged when one gramme of hydrogen and eight of oxygen (both gaseous under ordinary conditions) coalesce to form nine grammes of liquid water is close to 34,100 gramme degrees, corresponding with about 1·5 volts; but the limiting value of the counter E.M.F., $E - e'$, in this case exceeds 4 volts. On the other hand, when water is decomposed by feeble currents so that the evolved gases are absorbed or occluded by the electrodes, or are attracted thereto forming air-films over their surfaces, the values of $E - e'$ may

fall far short of 1·5 volt, being in certain cases barely appreciably greater than 0. It would thus seem that whilst the heat evolved during the condensation of 1 gramme of hydrogen and of 8 grammes of oxygen to the physical state of the gases occluded or attracted in the form of these films must jointly amount to something close to 34,100 gramme degrees at least, the energy requisite to break up water not into ordinary free oxygen and hydrogen, but into the *nascent* forms of these bodies, unmodified by subsequent coalescence or spontaneous modification must be equal to something not far short of three times that amount; whilst the total heat evolved during the subsequent modification of these elements (passage from atomic to molecular condition?) must represent at least 2·5 volts.

A large number of observations have been made (mostly published) on the relationships between the positive E.M.F.s generated in various kinds of voltaic cell when at their maximum, and the amounts of heat corresponding with the nett chemical changes ensuing between the electrolytes and electrodes. The general result of these investigations has been to show that in but few instances are the two values approximately coincident (say within a departure of $\pm 0{\cdot}1$ volt), and even in these cases very material fluctuations in the actual E.M.F. of an electromotor may be brought about by alterations in solution, strength, and plate surface nature that exert but little influence on the nett heat development. One conclusion deducible from this and other allied facts is that the seat of primary action in such cases lies at the junctions of the surfaces of the electrodes and fluids, and that the *modus operandi* of a voltaic cell is in certain respects closely akin to that of a thermo-couple or Peltier couple, consisting of two dissimilar forms of solid matter (metals, &c.) where conversion of sensible heat into current takes place, or *vice versa.* In fact the actual maximum E.M.F.s set up in such cells as those examined (mostly after Daniell's construction, *e.g.*, $Zn \mid ZnSO_4 \mid CuSO_4 \mid Cu$) are found to be conveniently represented by assigning to each given metal immersed in a given solution of one of its salts a numerical value, or *thermo-voltaic constant* (analogous to the thermo-electric values assignable to metals, &c., when used in thermo-electromotors), and adding the algebraic difference between the values for any two given pairs of metal and salt (which difference may be a positive or negative quantity) to the value in volts corresponding with the heat evolution due to the nett chemical change. According as this difference is plus or minus, the E.M.F. actually set up exceeds or falls short of the amount due to the nett chemical change. Relatively to zinc, some metals have thus in general a negative and others a positive thermo-voltaic constant assignable, no matter what the class of salt employed. The cells where the algebraic difference between the thermo-voltaic constants is positive in sign are characterised by the peculiarity that in the production of a current by them sensible heat must become converted into current energy, causing cooling of the cell; for with a large external resistance more work is done outside the cell than corresponds with the heat development due to the nett chemical change. With cells where this difference is negative in sign, the reverse holds so long as the numerical value of the difference is not greater than that corresponding with the difference in heat of formation between the two fluids surrounding the plates; the cell in this case being warmed by the passage of the current, and less external work being done than corresponds with the nett heat development due to chemical change. When, however, the numerical value of the negative algebraic difference between the thermo-voltaic constants exceeds that corresponding with the difference in heat of formation, the remarkable result ensues that the current circulates in the direction opposite to that predicable from the relative heats of formation of the fluids in the cell; so that not only is there absorption of heat in the cell itself, due to the character of the chemical changes occurring as the current passes, but, further, any work done outside the cell must be at the expense of the sensible heat of the cell itself.

5. *On the Sensitiveness to Light of Selenium and Sulphur Cells.*[1] *By* SHELFORD BIDWELL, *M.A., LL.B.*

The fact first announced by Mr. Willoughby Smith in 1873 that the electrical resistance of crystalline selenium is temporarily diminished by the action of light has been fully confirmed by subsequent experimenters. Of the many investigations which have been undertaken in reference to this subject, by far the most valuable and exhaustive are those of Professor Adams and Mr. R. E. Day, an account of which was published in the 'Philosophical Transactions' for 1877. These gentlemen arrived at the conclusion that the diminution in the resistance of selenium might be accounted for by the fact that light promotes crystallisation, for in changing to the crystalline state selenium becomes a better conductor of electricity. They also state their belief that selenium conducts electrolytically; but it may be inferred from the paper—and was indeed explained by Professor Adams himself at the meeting of the Physical Society on June 13 last—that the authors did not suppose that actual electrolysis occurred, but rather that the molecular structure or crystalline condition of the substance was altered or modified by the action of a current of electricity in such a manner as to produce effects analogous to those which would have occurred if the selenium were an electrolyte, and actually decomposed by the current.

A new form of selenium cell has recently been described by Mr. C. E. Fritts, of New York. A thin film of selenium is spread upon a plate of some metal, such as brass or copper, with which it will form a chemical combination. The selenium is melted and crystallised under pressure, and, when cold, its surface is covered with a film of gold-leaf sufficiently thin to transmit light. The metal plate and the gold-leaf form the two electrodes of the cell, the resistance of which is varied by the action of the light which passes through the gold-leaf.

Upon reading this description, it occurred to the author that the conduction of selenium, when prepared in the form of cells, might be in reality, and not merely in appearance, electrolytic. Selenium will, he believes, combine more or less readily with all metals, the combination being assisted by heat. And in the preparation of selenium cells it has been the usual, if not the universal custom, to submit the selenium to prolonged heating while in contact with metallic electrodes. This operation is generally called 'annealing,' and the undoubted fact that it diminishes the resistance of the selenium and increases its sensitiveness to light has been explained by supposing that the process is favourable to perfect crystallisation. The author suggests as an alternative explanation that the prolonged heating, by promoting the combination of the selenium with the metal of the electrodes, results in the formation of a selenide which completely surrounds the electrodes, and is perhaps diffused to some extent throughout the selenium when it is in a liquid condition; and that the apparently improved conductivity of the selenium, together with the electrolytic phenomena which it exhibits are to be accounted for by the existence of this selenide. It was found that while the specific resistance of the selenium contained in a well-annealed cell having copper electrodes was ·9 megohm, that of a similar piece of selenium annealed in a glass mould without contact with any metal was as much as 2,500 megohms. This enormous difference is to be attributed to the presence of selenide of copper in the selenium of the cell.

The above hypothesis has not been submitted to the test of direct experiment, but certain indirect evidence in support of it has been forthcoming. Selenium is an element which, in its properties, closely resembles sulphur, and many unsuccessful attempts have been made to develop in sulphur that peculiar sensitiveness to light which is such a remarkable characteristic of selenium. It occurred to the author that if this property of selenium were really due to the accidental existence of metallic selenides, then the admixture with sulphur of metallic sulphides might be expected to lead to similar effects. Several cells were therefore constructed, in which selenium was replaced by sulphur containing a proportion of silver sulphide,

[1] Published *in extenso* in the *Electrician*, Sept. 18, 1885, and in the *Chemical News*. See also *Phil. Mag.*, Aug. 1885.

the electrodes being formed of silver wire, and they all turned out to be more or less sensitive to light, and to exhibit other properties of annealed selenium.

When, as in the case of these cells, a current of electricity passes between silver electrodes through a mass of sulphide of silver, silver will be deposited upon the cathode, and sulphur upon the anode. Now sulphur has an enormously high resistance, and the existence of a mere film of free sulphur upon one of the electrodes would be sufficient to stop the current altogether. The current is not, in fact, stopped, because the deposited sulphur combines with the silver of the anode, merely adding a new layer to the electrolyte. Thus the metal of the anode gradually combines with the sulphur of the electrolyte, and the conductivity of the arrangement will depend, to a great extent, upon the facility with which this combination is effected. It might therefore be expected that the resistance of a sulphur cell with silver electrodes would be diminished by any influence which assisted the combination of silver with sulphur. Experiment shows that such an influence is exerted by light.

But it is not perhaps necessary to assume that the effective action of light is confined entirely to the electrode. It seems reasonable to suppose that any circumstances which are favourable to the union of two substances when they have a tendency to unite would also be favourable to their separation when from any cause they have a tendency to separate. If, then, as is commonly supposed, electrolysis involves a series of decompositions and recompositions, both these processes would be assisted by the same agency which, under ordinary conditions, favours the union of the constituents of the electrolyte. The electrolysis of silver sulphide may therefore be assisted by light, and its electrolytic resistance at the same time diminished.

Although results similar to those above described have not yet been obtained when other metals than silver have been used in conjunction with sulphur, the author believes it probable that the action of light upon the resistance of selenium in conjunction with any metal whatever with which it forms a sensitive combination is of a nature analogous to that which occurs in the case of sulphur and silver.

---

6. *On the Generation of a Voltaic Current by a Sulphur Cell with a Solid Electrolyte.*[1] *By* SHELFORD BIDWELL, *M.A., LL.B.*

While observing the secondary or polarisation currents, which are generated by sulphur cells (as by those made with selenium), after being disconnected from a battery, certain effects were noticed which seemed to indicate that when the electrodes consisted of two different metals, a sulphur cell might be capable of originating an independent or primary current. Experiments were therefore made with the object of investigating this point, and some of the results obtained are here given, though without any attempt to explain them, or to connect them together by a complete theory. They appear, however, to possess sufficient interest to render them worthy of record from the fact that no voltaic arrangement with a solid electrolyte has hitherto been constructed which—at least at ordinary temperatures—was capable of producing the smallest effect upon the most delicate galvanometer.

A plate of copper about one inch square was heated, and upon it was spread a mixture consisting of five parts of sulphur and one part of sulphide of copper. A plate of silver previously heated was then laid upon the melted mixture, and the two plates were squeezed together, thus forming a sandwich-like cell. When this cell, after cooling, was connected with a reflecting galvanometer, the spot of light was violently deflected off the scale. From very careful measurements it appeared that the E.M.F. of the cell was ·0712 volt, and its internal resistance 6537 ohms. The direction of the current was from the silver through the electrolyte to the copper, and there could be no doubt that it was of a voltaic nature. After the cell had been in existence for about three months, its E.M.F. had not materially fallen off.

[1] Published *in extenso* in the *Electrician*, September 18, 1885, and in the *Chemical News*. See also *Phil. Mag.* October, 1885.

The current was small owing to the great internal resistance of the cell, and attempts were made to reduce this resistance by diminishing the proportion of free sulphur. But it was found that when the resistance was reduced in this manner the E.M.F. was also reduced, and when there was nothing but simple copper sulphide between the plates, there was no sensible E.M.F. whatever.

Another cell was made in which powdered silver sulphide without any free sulphur was compressed between plates of silver and copper. This arrangement generated a current, the direction of which was opposite to that produced by the cells above described, but the E.M.F. rapidly fell off, and in three or four days had almost completely disappeared.

When a similar cell was constructed in which the silver sulphide was mixed with sublimed sulphur and placed in the form of a powder between the plates, the direction of the current was, as with simple silver sulphide, from copper to silver. But if the mixture was first fused and the plates between which it was compressed heated, the current generated by the cell when cold was in the reverse direction. Sulphide of copper was undoubtedly formed in the process of construction.

Consideration of these results led the author to believe that the sole function of the free sulphur in the copper sulphide cell was to form a film of silver sulphide by direct combination with the silver plate. A cell was therefore made as follows:—A layer of copper sulphide was spread upon a plate of copper, a polished steel plate was laid upon the sulphide, and the whole was strongly compressed in a vice. The steel plate was then removed and a thin layer of silver sulphide was spread upon the smooth surface of the copper sulphide. The cell was completed by pressing a silver plate upon the silver sulphide. This was found upon trial to give a current which, with an external circuit of low resistance, was many times stronger than that generated by any of the cells previously made. Its action was probably analogous to that of a Daniell's cell consisting of plates of zinc and copper in solutions of zinc sulphate and copper sulphate. The quantity of the copper sulphide would be gradually diminished, copper being deposited on the copper plate, while the quantity of the silver sulphide would continually increase with consumption of the silver.

A very curious experiment observed in the course of the experiments was the following:—If a battery current was passed for a short time through a cell containing two silver electrodes embedded in a mixture of sulphur and copper sulphide, the cell after being disconnected from the battery generated a current of very short duration (not impossibly due to thermo-electric action) in the direction opposite to that of the battery current; and this current, which rarely lasted for more than two or three minutes, was followed by another which was in the same direction as the battery current, and was generally maintained for several hours.

---

7. *A Theory of the Connection between the Crystal Form and the Atom Composition of Chemical Compounds.*[1] *By* WILLIAM BARLOW.

The author bases a theory of the origin of the symmetry of crystals upon the hypothesis that the different kinds of chemical atoms of a crystallising body so far preserve their individuality in the combined state as to personally attract or repel one another differently.

His theory is that liquid matter in the act of crystallising, just before solidification takes place, has the chemical atoms of different kinds which compose it symmetrically arranged in space with respect to one another, and that this symmetrical disposition of the atoms is the direct consequence of different degrees of attraction and repulsion exercised by the different kinds of atoms during fluctuations in the distances between them which are caused by waves of alternate condensation and rarefaction traversing the mass. He supposes that crystallisation occurs only in those cases in which the different kinds of atoms are present in such proportions as will admit of the necessary symmetrical arrangement.

[1] Published *in extenso* in the *Chemical News*, January 1 and 8, 1886.

After having argued the probability of the theory from first principles, the author traces several systems of symmetrical arrangement for various different atom proportions, and points out that these systems are in harmony with the known crystal forms. The pair of systems which he derives for the atom proportions of quartz have spiral dispositions of the same kind of atom, right-handed in one, left-handed in the other, such as may account for the production of right-handed or left-handed rotation of a polarised ray by crystals of the substance.

The cause of dimorphism is suggested, and symmetrical systems of arrangement of the atoms indicated for the dimorphic forms calc-spar and aragonite.

The different expansion in different directions of crystals not of the regular system is explained.

The phenomenon of twin crystals is shown to be in harmony with the theory.

A general theory of isomorphism is submitted; the case of isomorphism of ammonic sulphate and potassic sulphate being specially referred to.

8. *On the use of Sodium or other soluble Aluminates for softening and purifying hard and impure water, and deodorising and precipitating sewage, waste water from factories, &c. By* F. MAXWELL LYTE, *F.C.S.*

Roscoe gives the formula for sodium aluminate as $Na_2Al_2O_4$, and this nearly agrees with the composition of the soluble portion of the crude salt. But, owing to its tendency to lose alumina on keeping in solution, even in closed bottles, and to the invariable presence of soluble silicates, the dissolved salt has practically rather the formula $Na_6Al_4O_9$.

Sodium aluminate is decomposed by all soluble acids and acid salts, and even by many strictly so-called neutral salts, among them being the sulphates, chlorides, and nitrates of the earthy and heavy metals. In this latter case a corresponding portion of earthy or metallic hydroxide is liberated, or rather the earthy or metallic oxide remains so loosely combined with the precipitated alumina that it is practically free even to the point of being decomposed by carbonic acid, with the formation of a carbonate of the base it contains, thus destroying a like amount of temporary hardness if present, just as the aluminate itself has already destroyed a certain number of degrees of permanent hardness. Thus (if we adopt Roscoe's formula)—

$$Na_2Al_2O_4 + CaSO_4 + CO_2 + 3H_2O = Na_2SO_4 + 1CaCO_3 + Al_2(HO)_6.$$

The aluminium hydroxide takes down several times its own weight of organic matter, and thus may be produced—

(A) Precipitation of any organic impurity.
(B) Destruction of the permanent hardness.
(C) Destruction of the whole or part of the temporary hardness.

If the permanent and temporary hardness balance one another—*i.e.*, are equal in amount—an addition of aluminate only sufficient for the permanent hardness will gradually destroy both it and a like number of degrees of temporary hardness.

But if, as however is not often the case, the permanent hardness so far exceeds the temporary that there is not sufficient carbonic acid in solution to throw down as carbonate all the lime or other base producing the permanent hardness, a little sodium bicarbonate may be added, or, in order to keep down to a minimum the soluble sodic salts, a little phosphoric acid.

If the temporary hardness be in excess, it may be destroyed by Clark's method, or a little more aluminate may be added.

The time required for the precipitation of the aluminium salts and formation of the calcium and other carbonates, varies with different waters from a few minutes to a few hours, so that where time is an object it may be advisable to use some kind of rough filter. Indeed water so softened and purified passes easily and filters perfectly. Where water is contaminated with organic substances, but contains no appreciable hardness, or where it is desired to retain its hardness so as not to lose

its freshness, the sodium aluminate may be precipitated with aluminium sulphate, when the following reaction takes place:—

$$3Na_2Al_2O_4 + Al_2(SO_4)_3 18H_2O = \\ 3Na_2SO_4 + 4Al_2(HO)_6 + 6H_2O.$$

Indeed as the decomposition of the insoluble aluminate formed only takes place slowly, it is best to use this method in addition, even when adding the aluminate alone for softening, in all cases where much organic matter is present which it is desired to get rid of, and thus it is very applicable to the purification of sewage, waste waters from factories, &c. Its advantages consist—

(1) In its economy over every other known method of precipitation by aluminium hydroxide.

(2) The comparatively harmless nature and small proportion of the salt left in solution.

The usual way of obtaining the hydroxide is by aluminium sulphate and lime or chalk. But the sulphate (even the pure crystallised salt) contains only 15·44 per cent. of alumina (the commercial salt about 2 per cent. less), while sodium aluminate contains 52½ to 62½ per cent. and even the crude salt of commerce now obtainable abroad 33 per cent., so that a very much smaller quantity of the latter will suffice to produce a given quantity of hydroxide. Again, by using the sulphate with any salt other than the aluminate, the quantity of matter left in solution would be greatly increased, while in the case of lime or chalk with sulphate the effluent would possess that objectionable quality, 'permanent hardness.'

As to the question of cost, sodium aluminate has never been manufactured in England on a large scale, so that its price at present is abnormally high, though there is reason to believe that ere long it will fall considerably. As it is, where water possesses 20 degrees of hardness—*i.e.*, 10 permanent and 10 temporary—it can be freed from both these, as well as from any organic matter, for about 2*d.* per 1,000 gallons. Practically, and using the crude salt, the expenditure in the above case would be only just over 1 grain per gallon and per degree of hardness. The simple purification of water or sewage would be considerably less.

In experimenting practically with the above process for purifying sewage and waste waters it must be borne in mind, first, that great care must be taken to obtain a proper aluminate; and, secondly, that the salt should *not* be previously dissolved, but added, finely powdered, to the liquid it is desired to purify.

5. *The Size of Molecules.* *By* Professor A. W. REINOLD, *M.A.*, *F.R.S.*

The four lines of argument by which Sir W. Thomson has been led to form an estimate of the size of a molecule are, briefly, as follows:—

1. *Argument from the Refractive Dispersion of Light.*—If transparent substances like water, glass, &c., were infinitely homogeneous, the velocity of propagation of light through them would be independent of the period of vibration or wave-length. The fact that the velocity of propagation does depend on the period is irrefragable proof that such transparent substances are not infinitely homogeneous—*i.e.*, the coarse-grainedness of such substance is comparable with the wave-length of light. Cauchy was the first to arrive at this conclusion, but his theory leads to results altogether untenable. The same general principle is, however, applicable, and by making certain assumptions as to the connection between the ether and the heavier particles of matter, results may be obtained in agreement with those derived from other considerations.

2. *Argument from the Phenomena of Contact Electricity.*—If a plate of zinc and a plate of copper be brought into contact with each other, they become oppositely electrified and attract each other. Let the plates be each a square centimetre in area, and, after being made to touch, let them be brought to a distance of 10^{-8} centimetres from each other. The work done by electrical attraction while the plates are allowed to approach each other is about $2 \times 10^{6} \times 10^{-8} = 2 \times 10^{-2}$ centimetre-grammes. If now a third plate, of copper, be similarly placed upon the zinc platean, equal additional amount of work will be done by electrical attraction, and by making a pile of plates, alternately of zinc and copper, an amount of work will be done by electrical attraction proportional to the number of plates employed. Suppose a pile so constructed of 100 millions and one plates, 50 millions and one of zinc, and 50 millions of copper, each plate being the hundred millionth of a centimetre thick, and the distance between the plates the 100 millionth of a centimetre. The volume of the metal will be a cubic centimetre, and its mass 8 grammes. The work done by electrical attraction will be 2×10^{6} centimetre-grammes, or, $\frac{1}{4} \times 10^{6}$ centimetre-gramme per gramme of metal. To raise the temperature of 1 gramme of zinc or copper, the heat required is equivalent to 4030 centimetre-grammes. Hence the work done by electrical attraction would, in the form of heat, raise the temperature of the mass by $\frac{1}{4} \times 10^{6} \times \frac{1}{4030} = \frac{10^{6}}{16{,}120} = 62°$ C, which is not improbable according to our present knowledge of the heat of combination of zinc and copper. By supposing the plates and intervening spaces to be made yet four times thinner, it is shown, in a similar manner, that the temperature attained would be 990°. A result requiring more heat than is produced by the chemical union of copper and zinc. Hence plates of zinc and copper $\frac{1}{300{,}000{,}000}$ centimetres thick, placed close together alternately, form a near approximation to a chemical combination, if indeed such plates could be made without splitting atoms. This argument, therefore, gives $\frac{1}{30}$ M. (M = millionth of a millimetre) as the diameter of a zinc or copper particle.

3. *Argument from Liquid films.*—The surface tension of water is 81 dynes per centimetre, corresponding to about 8 milligrammes per millimetre. Therefore in the case of a water film with two faces the contractile force is 16 milligrammes per millimetre. Hence the work done in stretching a film of water, measured in milligramme-millimetres, is 16 times the number of square millimetres by which its area is increased. But the film is cooled in being stretched, and Sir William Thomson has shown that half as much energy must be supplied to the film in the form of heat to maintain its temperature constant. Hence the intrinsic energy of a mass of water in the shape of a film kept at a constant temperature is increased 24 milligramme-millimetres for every square millimetre added to its surface. Starting with a film of a thickness of one millimetre, and supposing it to be stretched until its area is increased 10,000 fold, the heat equivalent to the work done in stretching it, supposing the temperature to remain constant, is calculated. It is thus shown that work spent in stretching this film until its thickness is $\frac{1}{10{,}000{,}000}$ millimetre, would, in the form of of heat, cause a rise in temperature sufficient to vaporise the

film. This amount of work is far more than can be admitted, and the conclusion is inevitable that a water film falls off greatly in its contractile force before it is reduced to a thickness of $\frac{1}{10,000,000}$ millimetre. Such a falling off in the contractile force would indicate that there are not several molecules in this thickness of water.

4. *Argument from the Kinetic Theory of Gases.*—Supposing the molecules of a gas to be hard elastic globes all of one size, influencing one another by actual contact only, each molecule will move along in a zigzag path consisting of rectilinear portions, with abrupt changes of direction. Clausius has shown the average length of a free path of a particle, from collision to collision, to bear to the diameter of each globe, the ratio of the whole space in which the globes move to $6\sqrt{2}$ times the sum of the volumes of the globes. Or if λ be the average length of free path, σ = diameter of a globe, v = volume of the globes in 1 c.c. of gas, then $\sigma = 6\sqrt{2}\, v\, \lambda$. Since it is inadmissible to suppose that, in the liquefaction of any of the ordinary gases, they could be made 40,000 times denser than at ordinary temperature and pressure, without reducing the whole volume to less than that of the sum of the globes, the free path must not be more than 5,000 times the diameter of the gaseous molecule. The average length free path of each molecule from collision to collision in the case of oxygen, nitrogen, or air, has been shown to be $\frac{1}{100,000}$ of a centimetre. The diameter of the gaseous molecule, therefore, cannot be less than $\frac{1}{500,000,000}$ centimetre, *i.e.*, 2×10^{-9} or $\frac{1}{50}$ M (millionth of a millimetre). Nor can the number of molecules in a c.c. of gas be greater than 6×10^{21}. Since the densities of known liquids and solids are from 500 to 16,000 times that of air, at ordinary pressure and temperature, the number of molecules in a c.c. may be from 3×10^{24} to 10^{26}. Assuming a cubic arrangement of molecules, the distance from centre to nearest centre in solids and liquids may be estimated at from $\frac{1}{140,000,000}$ to $\frac{1}{460,000,000}$ millimetres.

These four lines of argument show that in liquids and transparent solids the mean distance between the centres of contiguous molecules is something between $\frac{1}{10}$th and $\frac{1}{200}$th of a millionth of a millimetre.

Quite recently Professor F. Exner has shown that v in the formula $\sigma = 6\sqrt{2}\, v\, \lambda$, mentioned above, may be calculated in another way. Starting from Faraday's assumption that a dielectric consists of particles of conducting substance distributed throughout its mass and separated from each other by absolutely non-conducting (void) spaces, and supposing v = the sum of the conducting particles in 1 c.c. of dielectric, Clausius has shown, supposing the particles to be spheres, the following simple relation to hold between v and the specific inductive capacity of the dielectric viz., $v = \frac{K-1}{K+2}$. Further, according to Maxwell's theory, $K = n^2$, where n = the refractive index of the substance. Hence in the case of gases the formula $v = \frac{K-1}{K+2} = \frac{n^2-1}{n^2+2}$ may be applied. The values obtained by this method for the diameter of a molecule are smaller than those obtained by the other methods, but of the same order of magnitude.

The author goes on to give a brief account of the experiments on soap films, conducted by himself conjointly with Professor Rücker ('Nature,' vol. xxxii., p. 210), the results of which, even when the highly complex character of the liquid employed is considered, are not out of accord with the estimate of Sir W. Thomson as to the size of molecules, although the upper limit given in 1873 by the latter (viz., $\frac{1}{5}$ M), is probably too high.

---

6. *An approximate determination of the Absolute Amounts of the Weights of the Chemical Atoms.* *By* G. Johnstone Stoney, *D.Sc., F.R.S.*

Several inquiries (see Professor Loschmidt, 'Zur Grösse der Luftmolecule,' *Academy of Vienna,* Oct. 1865; G. Johnstone Stoney on 'The Internal Motions of Gases,' *Phil. Mag.* August, 1868; and Sir William Thomson on 'The Size of

Atoms,' *Nature*, March 31, 1870) have led up to the conclusion that the number of molecules in each cubic millimetre of a gas at atmospheric temperatures and pressures is somewhere about a unit-eighteen (10^{18}). Hence, the number of molecules in a litre will be about a unit-twenty-four (10^{24}). Now, a litre of hydrogen at atmospheric pressures and temperatures weighs, roughly speaking, a decigramme There is no advantage in taking account of the ratio of 1·2 decigramme to 1 decigramme. Hence, the mass of a molecule of hydrogen, or weight, as it is called by chemists, is a quantity of the same order as a decigramme divided by 10^{24}—*i.e.* a twenty-fourth decigramme, which is the same as the twenty-fifth grammet. (The grammets are the decimal subdivisions of the gramme, of which the first is the decigramme, the second the centigramme, and so on.) Hence, the mass of the chemical atom of hydrogen may be taken to be about half the twenty-fifth of the grammets. There is no use in retaining the co-efficient 'half' in an estimate in which we cannot be certain to a unit that we have assigned the right power of 10, and we may, therefore, for the sake of simplicity, take the twenty-fifth grammet itself as being such an approach as we can attempt to the value of the mass of the chemical atom of hydrogen.

Having obtained the mass of one atom, that of hydrogen, the masses of the atoms of the other simple substances bear the ratios to this that are assigned to them in the table of atomic weights, and the masses of molecules of compounds can be derived directly from these in accordance with their formulæ, so that all are approximately known.

---

7. *On Macromolecules (Molecules of Matter in the Crystalline State as distinct from the Chemical Molecule), and determinations of some of them.* *By* G. JOHNSTONE STONEY, *D.Sc*, *F.R.S.*

The molecule of a crystal is usually found, in the few cases in which an investigation is possible, to include several chemical molecules. On this account the author has suggested that they be called macromolecules, as in reference to them the chemical molecule is a sub-molecule.

In a communication made two years ago to the British Association, it was shown that although each chemical atom of a solid may be in a state of internal motion, this motion must be such that a point can be assigned within each atom (and which is determined by an integration similar to that by which centres of gravity are determined) which point is a fixed point in solids, and a travelling point if the atom be an atom of a liquid or gas. This for convenience may be called the centre of the atom. In a crystal, these centres are all in fixed positions and at definite distances asunder, so that a diagram may be conceived consisting of these points, with lines connecting them wherever the corresponding atoms are chemically in combination. The chemical formula limits geometrically the number of positions relatively to one another in which these points can stand within one chemical molecule.

The only hypothesis that needs to be made is at this stage and the next, at both of which it is assumed that the bonds or connections between the chemical molecules of a solid are identical with the bonds found by Chemistry between the atoms of chemical molecules, being some not used in forming that particular sub-molecule.

By this hypothesis the diagram can be extended to a group of chemical molecules, and, as before, there is geometrically only a limited number of such diagrams possible.

Finally, these groups or macromolecules are again connected together by chemical bonds not yet employed, and these final connections must be such that the resulting form &c. are identical with the observed crystalline form with all its faces and with its cleavage planes, &c. All these when known furnish conditions that limit the number of possible arrangements at the preceding stages, and if the number of such conditions be sufficient, or where the crystalline form is sufficiently complicated, and especially where hemihedral faces occur, they give an indication as to which of the possible arrangements at the preceding stages is the real one. In a few cases it has been possible in this way to make out with considerable

probability what the arrangement at each step is, and thus to trace a connection between the chemical constitution and the crystalline form, &c.

Thus in iron pyrites, FeS_2, the hemihedral form with parallel faces which is characteristic of this mineral, and which is from it called the pyritohedron, can be traced on from the chemical molecule FeS_2 through a macromolecule which includes six of these as sub-molecules, and which is connected with the other similar macromolecules in a regular way.

So, again, the general form and tetrahedral hemihedralism which are found in boracite can be traced from its formula,

$$3MgO, 4B_2O_3,$$

through macromolecules each of which contains four of these chemical molecules.

And, again, the two kinds of hemihedralism, the right-handed and the left-handed, which present themselves in different specimens of quartz, can be traced from the chemical molecule SiO_2 through a macromolecule which contains six of these connected in one or other of two possible ways, and thence on to the two crystalline forms of the perfect crystal that present themselves.

There is therefore reason to believe that in each of these crystals the macromolecule or crystalline molecule consists of several chemical molecules, and must be carefully distinguished from the latter, containing in iron pyrites six, in boracite four, and in quartz six, chemical molecules.

8. *On the Dilatancy of Media composed of Rigid Particles in Contact.* *By* Professor Osborne Reynolds, *F.R.S.*—See Section A, p. 896.

9. *On the Evidence deducible from the Study of Salts.* *By* Spencer U. Pickering.

In this paper the author dealt with the evidence as to the molecular weights of salts, derived from a study of the composition (1) of hydrated salts; (2) of basic salts; (3) of double salts. He also criticised the evidence deducible from experiments on hydration, dehydration, and the vapour tension of hydrated salts, and finally examined the conclusions drawn from the calorimetric investigations of such compounds. The conclusions arrived at by the author are, that, although in a few isolated cases the molecular weight obtained would appear to be greater than the analytical results necessitate, still in a vast majority of cases there are no grounds for multiplying these weights, and, indeed, there is a considerable mass of evidence in favour of adhering to the simplest possible formulæ. Such a conclusion may, at first sight, appear opposed to conclusions drawn from other sources. On the one hand the author considers it undeniable that if we succeed in determining the number of replaceable portions of the elements in any compound, we determine *ex hypothesi* the number of atoms in the molecule—that is the molecular weight—and although the data at our disposal at present are of the most meagre description, they nevertheless seem to point incontestibly to the simplicity of these molecules. On the other hand, considerations based on the crystalline form and other physical properties of bodies force on us the conclusion that liquid and solid molecules are in all probability of a very complicated nature, certainly more complicated than gaseous molecules. Both these conclusions the author considers to be reconcilable with one another, and contends that because the smallest particle of a substance which enters into a chemical reaction may be simple, there can be no reason why many of these particles may not agglomerate and act in unison as regards certain physical forces. That this agglomerate does not act as a unit towards chemical forces would simply imply that the force which unites the individuals constituting it is not chemical force, or is chemical force of such a weak nature that, in presence of the strong chemical agents we make use of, it is inappreciable. The molecule of a chemist is not necessarily identical with the molecule of a physicist.

10. *On the Molecular Weights of Solids and Salts in Solution.* *By* Professor W. A. Tilden, *D.Sc.*, *F.R.S.*

It seems to be generally agreed that bodies in the *solid* state consist of units or molecules which are very complicated and made up a of considerable number of such smaller aggregates as compose the molecules of gases. Accepting the conclusion, the author is disposed to go further, and to say that in any given case there appears to be no reason for limiting the number of small molecules which may thus be bound together to form the physical unit of a solid. The law of Dulong and Petit, and Neumann's law, according to which every elemental atom, whether free or in combination, has the same, or nearly the same, specific heat, point to a conclusion of this kind. The law of Dulong and Petit states that, approximately at least, the specific heat in the solid element is inversely as the atomic weight, or as *n times the atomic weight*. This seems to indicate that, since *n* may be made as large as you please, there is in solids of this kind, and in salts, &c., no difference between *molecule* and *mass*, and that the physical unit is the atom. The same kind of argument may be deduced from the facts known concerning the specific volumes and refraction equivalents.

Solid bodies according to this view are composed of atoms which are only distributed into molecules capable of taking up an independent state of existence when the body becomes fluid.

Such a hypothesis involves or implies another, viz., that chemical combination between atoms and the combination of molecules which ensues when a gas or a liquid returns to the state of solid are phenomena of the same nature. This agrees with the commonly recognised resemblance between the process of dissociation and the processes of fusion and of evaporation. In both the change is gradual and is dependent upon temperature, and both are directly measurable in terms of heat or some other form of energy. Another consequence of this view is that we must confine the idea of *limited* valency to gaseous substances. From the well known numerous double salts, and especially such compounds as the periodides of the organic bases, it appears, in the solid state, the elements and especially the non-metallic elemental radicles, are capable of developing an indefinitely large capacity for combination. None of these so-called molecular compounds exist in the gaseous state.

With regard to solutions there are many facts which indicate that the molecules of dissolved substances are smaller than those of solids. Thus it appears that the alums, the numerous double iodides and chlorides, and such compounds as racemic acid, exist only in the solid state. When they pass into solution they are resolved into their proximate constituents. To determine whether common salt in solution is NaCl or *n* times NaCl seems almost an insoluble problem. The question of water of crystallisation is related to this subject, and here we have some evidence, though conflicting. On the one hand we have the evidence of such experiments as those of Dr. Nicol on the molecular volumes of salts in solution, from which it appears that the water of crystallisation of a salt dissolved in water is not distinguishable from the rest of the water with which the salt is mixed. But if this means that when a salt such as copper sulphate, for example, is dissolved in water, the water combined in the crystal separates from it, leaving the salt molecule to wander free, the author can not assent to this view. By this hypothesis we can explain neither the colours of such solutions, nor the large evolution of heat which ensues on the introduction of such a salt in the anhydrous state into water.

The composition of the salt molecule in solution appears to be dependent chiefly upon temperature. If we dissolve in water a salt like common salt, which habitually crystallises without water of crystallisation, the salt molecule in solution at ordinary temperatures does not include the elements of water, in other words the salt dissolves in the anhydrous state. But if we take a salt such as sodium sulphate, the dissolved molecule retains the same amount of water as the crystals formed at the same temperature, whilst if the temperature is raised these molecules are gradually broken down until at a certain temperature all the salt molecules

present give up their water and become anhydrous. The author has now satisfied himself by experiment that this decomposition or dissociation is progressive and does not take place *per saltum*. Taking sulphate of sodium, which has its point of maximum solubility at 34° and above that point deposits the anhydrous salt, he has made determinations of the rate of cooling of a strong solution and finds the time-temperature curve to be parallel with that of water done under the same conditions. Calorimetric determinations of the heat of solution of the anhydrous salt at successive temperatures lead to the same conclusion.

11. *On the Molecular Constitution of a Solution of Cobaltous Chloride.* *By* Professor W. J. Russell, *Ph.D., F.R.S.*

A thin layer of cobaltous chloride gives an absorption spectrum consisting of two broad ill-defined bands. If the chloride be fused with potassium, sodium, or calcium chloride, the spectrum of these mixtures, both in the solid and fused state, is different from that of cobaltous chloride, alone and consists essentially of four bands, two of which are marked and characteristic. This same spectrum is obtained with solutions of cobaltous chloride in absolute alcohol, in amyl alcohol, in hydrochloric acid, and in glacial acetic acid. This spectrum would, therefore, appear to be that of cobaltous chloride in an altered molecular state. The spectrum of an aqueous solution is again different, and consists of one broad band nearer to the blue end than the other bands, but the addition of cobaltous chloride to such a solution, or of such bodies as possess an affinity for water, causes a reversion of the spectrum to that of the anhydrous cobaltous chloride. Heat also produces the same effect, and it would appear from these results that the anhydrous chloride can exist in aqueous solutions. The changes in the character of a spectrum of an aqueous solution produced by heat may be explained as arising from a dissociation of some of the hydrates existing in the solution, and the production of anhydrous cobaltous chloride. Further, the fact that those solutions containing the anhydrous salt more readily transmit the blue rays and absorb the red rays, whilst those containing hydrates in solution more readily transmit the red rays, would indicate that the molecule of the hydrate is smaller than that of the anhydrous salt. The action of water on the anhydrous salt, therefore, is not to form an additive compound, but to split the molecule of the anhydrous salt and form one in which water replaces cobaltous chloride.

1. *An Electro-centrifugal Machine for Laboratory use.*[1] *By* Alexander Watt, *F.I.C., F.C.S.*

This instrument, although in itself possessing no scientific interest, has been found so useful in the laboratory as to justify the hope that a description of it and a demonstration of its use may prove of interest.

The late Dr. Mohr, of Bonn, in his 'Titrirmethode' advocated the use of a centrifugal machine for the rapid drying of crystalline precipitates, for use in volumetric analysis, and although they are admirably adapted for such purposes, centrifugal machines are seldom seen in our chemical laboratories. It is possible that the neglect of this valuable addition to our laboratory apparatus is owing to the inconvenience involved in driving the machine at a high speed by means of the ordinary pulleys or other speed-increasing gear, especially when the rotation has to be kept up for a considerable length of time.

[1] Printed in full in the *Chem. News*, vol. 52, p. 232.

It therefore occurred to me, that by directly attaching an electro-motor to the revolving drum or basket (or table as in Mohr's instrument), the inconvenience attending the driving might be got over, and at the same time a combination of great efficiency would result, as the electro-motor like the centrifugal machine is most efficient when driven at a high speed.

The apparatus consists essentially of a basket or drum of perforated copper (it might be of iron, or other suitable metal, or of ebonite) slipped on to a cone attached to the spindle of a small electro-motor, and is held in position by means of a nut. The surrounding casing serves to catch the liquid driven out of the substance being dried. The electro-motor consists of a Siemens H armature, which revolves between the poles of an electro-magnet of soft iron. The centrifugal machine, as is well known, has many industrial applications. It is used in laundries and in the textile manufactures for drying wool and cloth, in dyeworks for drying feathers, and in the manufacture and refining of sugar, for the separation of the sugar crystals from the syrup, but it is only quite recently that chemical manufacturers have awakened to its value.

4. *The Action of Nitrous Gases upon Amyl Alcohol.* *By* J. Williams, *F.C.S., F.I.C., and* Myles H. Smith, *F.C.S.*

Having had occasion lately in the manufacture of amyl nitrite, to determine for commercial and manufacturing purposes the best mode of producing the largest possible result from a given amount of materials, the following results were obtained.

We should mention that in all the trials the same sample of amyl alcohol was employed. This had been well purified by washing, fractional distillation, and several distillations in the vapour of steam; it was therefore practically nearly pure, but may still have contained traces of ethylic and butylic alcohols, and perhaps other bodies.

The nitrous gases were produced by the action of nitric acid of various strengths upon arsenious acid. With the very strong acids it was necessary that the arsenious acid should be in lump to moderate the action.

It was found that the gas produced by nitric acid of sp. gr. 1500 was nearly entirely absorbed by the amyl alcohol, which when completely nitrified changed in colour from a bright yellow to a greenish-brown. The product, washed and distilled, gave only from 42 to 48 parts distilling under 100° C., about 85 parts under 120°, and remainder boiling at a considerably higher point. This result was very unsatisfactory, and proved that the gas produced by acid of this strength was nearly pure nitrogen tetroxide, which in contact with the amyl alcohol was split up into nitrous acid (producing less than one-half nitrite amyl) and nitric acid, producing higher products of oxidation.

Nitric acid of 1420 was then tried. Much of the gas was absorbed, but a considerable quantity of unabsorbable gas was produced, and the product yielded about 65 to 70 parts of a distillate coming over at 100° or a little above. This result, although better, was not at all satisfactory.

Nitric acid of 1350 gave a gas which contained a still larger proportion of unabsorbable gas, but ultimately yielded a product which gave on one occasion as much as 90 per cent. of distillate under 100°, and 95 under 105°.

When nitric acid of sp. gr. 1300 was employed, most of the gas obtained was unabsorbable, but a small percentage of absorbable gas was obtained, which

after some time was sufficient to complete the reaction. The product, washed and distilled, gave a result yielding as much as 95 per cent. of distillate under 100°.

It appeared evident from the experiments that acid of a medium strength, say 1350, was better adapted for our purpose than either very strong or very weak acid. That, in fact, the very strong acid produced little else than nitrogen tetroxide, and the very weak acid mainly nitric oxide. We determined to try a mixture of these two gases.

The nitrogen tetroxide was produced by acting upon arsenious acid by nitric acid of sp. gr. 1500, or, in a later experiment, by acid of 1520. The nitric oxide was made by adding nitric acid to nitrite of sodium, or, in the latter experiments, by acting upon copper turnings by nitric acid. The gases were allowed to mix in a glass vessel, care being taken to keep the nitric oxide in considerable excess. Under these circumstances the mixed gases were freely absorbed, some unabsorbable gas being of course given off. And the product when examined gave at first from 85 to 90 parts boiling under 100°, but in later experiments the result came up to 95 parts at 100° and 97 parts at 105°. This result, from the manufacturing point of view, was as perfect as we could desire.

It is not our wish to express any opinion as to the nature of the mixed gas, but can only record the fact, that it acts very much as we should expect nitrous acid gas (if it exists) would act upon amyl alcohol. That is a question, however, we leave for the consideration of others.

5. *On the Action of Water on Lead.* *By* A. H. Allen, *F.C.S.*

SECTION C.—GEOLOGY.

PRESIDENT OF THE SECTION—Professor J. W. JUDD, F.R.S., Sec. G.S.

THURSDAY, SEPTEMBER 10.

The PRESIDENT delivered the following Address:—

As this city is the only place within the limits of the Scottish Highlands where our Association holds its annual gatherings, it is fitting that the attention of those who meet in this Section should, on the present occasion, be specially directed to the grand problems of Highland geology. Six-and-twenty years have passed since the members of this Section assembled here, under the presidency of my dear friend, my revered master, Charles Lyell. Few now present can have actually listened to the stormy discussions of that memorable occasion, but all are familiar with the nature of the problems which in the year 1859 were here so keenly debated. It is true that the fires of these controversies have now almost died out, and from their ashes have arisen the new problems which confront us to-day; but it will not, I think, be without profit to direct your attention for a few minutes to those two subjects which constituted the 'burning questions' of that time—the age of the Crystalline Rocks of the Highlands, and the geological position of the Reptiliferous Sandstone of Elgin.

With respect to the first of these questions, there are especial reasons why I should briefly review the discussions which have taken place in connection with it. It was in the meetings of this Section of the British Association that the successive stages of the controversy were gradually developed. It was at a former meeting of the Association in this city that James Nicol submitted to the scientific world that splendid solution of a difficult problem, which is now universally admitted to have been the correct one. This university was, during the last twenty-seven years of his active, useful, and honoured life, the scene and centre of the labours of that profound but modest thinker to whom we owe so much. Lest it should seem presumption on my part to speak on the question, I may add that for some years before his death it was my good fortune to enjoy the friendship and confidence of the late Professor Nicol, with whom I had several opportunities of discussing the great questions at issue between himself and Murchison. Seeing, as I do to-day, his own great claims too often forgotten or ignored, I feel that should I, on this occasion, hold my peace—'the very stones would cry out.' It will indeed be an unfortunate day for our republic of science when the palm of recognition—withheld from him whom modesty and self-respect restrain from clamorous self-assertion—is permitted to be snatched away by the bold and noisy advertiser of his own claims.

Nearly seventy years ago, John Macculloch—that distinguished pioneer in Scottish geology—was able to prove that in our Western Highlands there exists a grand formation, made up of red sandstones and quartzite, both exhibiting unmistakable evidence of a sedimentary origin. He also pointed out that, associated with these red sandstones and quartzites, are beds of limestone, which are often altogether destitute of crystalline characters, and are sometimes bituminous, while they occasionally contain fossils.

Macculloch strongly insisted that this great system of strata, which covers large areas in Sutherland and Ross, extending also into some of the Western Isles, is distinct alike from the Old- and the New-Red Sandstone; he asserted that it belongs to a far older period than either of those formations, and, employing the phraseology of the early geologists, he gave to it the name of the '*Primary* Red Sandstone.'[1]

Macculloch showed clearly that the strata of his 'Primary Red Sandstone Formation' are often found resting unconformably upon the gneissose and schistose rocks of the Highlands; but that in other places they appear to be overlain conformably by, and even to alternate with, crystalline schists and gneisses. He was further able to state that the quartzites of his 'Primary Red Sandstone Formation' contain organic remains, some of which he correctly identified as the burrows of marine worms, while others he recognised as *Orthoceratites*.[2] It is almost painful to have to add that his want of appreciation of the value of palæontological evidence, a weakness which Macculloch shared with so many of the early Scottish geologists, prevented any attempt on his part at the correlation of this 'Primary Red Sandstone' with the rocks of other districts; and thus for more than forty years this important discovery remained almost entirely fruitless.

The next step in the history of our knowledge of these Highland strata which we have to record, was unfortunately a retrograde one. Sedgwick and Murchison, who visited the district in 1827, maintained that Macculloch had fallen into grievous error, and that his 'Primary Red Sandstone Formation' was in fact no other than an outlying part of the Old Red Sandstone.[3]

This view was strongly protested against by Hay Cunningham, who, writing in 1839, after a careful survey of Sutherland, demonstrated the justice of Macculloch's conclusions, and even went beyond that geologist in showing the very intimate connexion between the quartzite and limestone. He clearly illustrated by numerous sections the unconformity of the 'Primary Red Sandstone Formation,' consisting of red sandstone, quartzite, and limestone, upon the gneissose rocks, and the apparently conformable superposition to it of other schists and gneisses.[4]

Such was the state of geological opinion when, in the winter of 1854, the attention of geologists was recalled to this ancient formation of Macculloch by the discovery in it of fossils by one who fully recognised their value and importance—Mr. Charles Peach. These fossils, though imperfect, were sufficient to prove that the strata containing them must be of *Palæozoic* age.

Three of the leaders of geological science at that day appear to have been deeply impressed with the importance of this discovery of Mr. Peach's; but for a time, at least, the fruits of that discovery were missed, through the unfortunate retrograde teachings of Sedgwick and Murchison in 1827.

Hugh Miller, whose splendid researches in the Old Red Sandstone had made him ready to welcome any extension of its boundaries, suggested that the fossils of Durness might belong to the marine Devonian.

Roderick Murchison, who in his younger days had worthily conquered a kingdom in Siluria, and by successive annexations in his later years had sought to convert this kingdom into an empire—one which should embrace all the Lower Palæozoic rocks of the globe—was not unwilling to claim his native Highlands as part of this ever-growing realm.

James Nicol, who had been the first to discover graptolites in the rocks of the Scottish Borderland, and had thus demonstrated their Silurian age, was so struck by the resemblance of some of the slaty rocks of the Highlands to the fossiliferous shales of his native district, that, ten years before Peach made his important discovery, he had suggested the probability of the Highland schists and gneisses being

[1] *Trans. Geol. Soc.* ser. 1, vol. ii. p. 450, &c. *Western Isles of Scotland* (1819), vol. ii. p. 89, &c. *System of Geology* (1831).

[4] 'On the Geognosy of Sutherlandshire,' by R. J. H. Cunningham, M.W.S.; *Transactions of the Highland and Agricultural Society of Scotland*, vol. xiii. (1839).

simply the Borderland shales and greywackes in an altered state.[1] Hence Nicol, equally with Murchison, was prepared to accept the Silurian age of the Durness limestone, and of the rocks associated with it.

Murchison, still full of his old enthusiasm for discovery, determined to lose no time in putting to the test the truth of the suggestion made by his old friend Nicol and himself; and accordingly shortly before the meeting of the British Association, which was fixed to take place in the year 1855 at Glasgow, we find the two friends making their way into the wild district of North-west Sutherland.

Unfortunately the time was too short and the weather too unpropitious for the tasks they had set before themselves.

When this Geological Section assembled at Glasgow, Murchison declared his conviction that the limestone of Durness, which had yielded the fossils to Mr. Peach, was of Silurian—that is, as he employed the term, of Lower Palæozoic age. But he, at the same time, maintained the truth of his old views, that the red sandstones of Applecross and Gareloch are in reality nothing but Old Red Sandstone,[2] and in this latter contention he received the warm support of Sedgwick, who was also present at the meeting.[3]

Nicol, on the other hand, appears to have been greatly dissatisfied with the results of this hasty and inauspicious journey to Sutherland. While, however, withholding his judgment as to the age of the several rock-masses, he insisted, in opposition to the views of Murchison and Sedgwick, that the whole of the vast series of Red Sandstones in Applecross and Torridon is, as Macculloch showed, inferior to the quartzite and limestone.[4]

In the summer of the next year, 1856, Nicol, so soon as he was released from his teaching work in this university, hastened back to the Western Highlands to try and resolve some of the doubts which troubled him concerning the age and succession of the strata. This summer's labour was productive of great and important discoveries. In the first place, he was able to completely confirm the conclusion of Macculloch and Hay Cunningham, that *all* the Red Sandstone of the Western Highlands, with the exception of some small patches of 'New Red,' belong to an old formation underlying the quartzite and limestone. But his researches also enabled him to show that Macculloch's 'Primary Red Sandstone' in reality consists of *two* formations, the lower—to which he subsequently gave the name of the 'Torridon Sandstone'—lying unconformably on the gneiss, and the upper (consisting of quartzite and limestone, containing fossils), resting everywhere unconformably upon, and overlapping, the sandstones.[5] It is a very noteworthy circumstance that while Nicol admitted the accuracy of the descriptions of Macculloch and Hay Cunningham which seemed to point to a conformable superposition of beds of gneiss to the quartzite and limestone, the results of this first summer's work had already raised serious misgivings in his mind as to the correctness of this conclusion, for he wrote as follows:—'The fact of the overlying gneiss having been metamorphosed *in situ*, and not pushed up over the quartzite, is one requiring further investigation.'[6] It is not surprising, however, to find that Nicol was so staggered by the magnitude of the faults which would be required to bring about such a result, that for more than a year he hesitated to accept this, which we now know to be the true explanation of the phenomena.

There was a suggestion—and it was nothing more than a suggestion—made by Nicol at this time, which has often been very unfairly quoted to his disadvantage. Convinced that Macculloch was right as to the infraposition of the Torridon Sandstone to the quartzite and limestone, and strongly inclined to accept

[5] Col. Sir Henry James is said to have made similar observations during the same season, the summer of 1856, and to have communicated them to Sir Roderick Murchison by letter. But there can be no doubt that Nicol's discovery was made quite independently, and he was the first to publish it.

[6] *Quart. Journ. Geol. Soc.* vol. xiii. (1857), p. 35.

Murchison's confident assertion that this Torridon Sandstone was simply the 'Old Red,' Nicol pointed out that the only possible way of harmonising these two views was to suppose that the quartzites and limestones were of Carboniferous age; and he showed that the imperfect fossils which had been up to that time obtained at Durness were not sufficient to negative such a supposition.[1]

But during the summers of 1857 and 1858, Nicol continued his labours in the Western Highlands, with the result of clearing away many of his difficulties and perplexities. Murchison, too, had revisited the district, and seen that his idea of the 'Old-Red' age of the Torridon Sandstone would have to be finally abandoned, and that Macculloch's views, as amended by Nicol, concerning the relations of the Highland rock-masses must be accepted. Salter, too, examining more perfect specimens of fossils, which had in the meanwhile been obtained from the Durness limestone by the indefatigable Mr. Charles Peach, showed that they were certainly of *lower* Palæozoic age (Silurian of Murchison).

The position taken up by Murchison, and on which he made his final stand, was simply arrived at by combining the stratigraphical conclusions of Macculloch and Nicol with the palæontological results of Peach and Salter.

Murchison attended the meetings of this Association at Dublin in 1857, and at Leeds in 1858, on both occasions making use of the opportunity for explaining in detail his ideas concerning the age and succession of the Highland rocks. On the latter occasion, he challenged his old friend Nicol to meet him at the forthcoming meeting at Aberdeen to discuss the question, and the challenge was accepted.

When Murchison arrived at this city, in September 1859, he brought with him a redoubtable champion in the person of Professor (now Sir Andrew) Ramsay, the director of the Geological Survey, who had been conducted to Assynt and shown the section there. It may perhaps serve as a caution against hasty generalisations, drawn from a single section imperfectly examined, to remember that so excellent a field-geologist, as Ramsay undoubtedly was, not only failed to see the weakness of Murchison's position, but threw all the weight of his great authority into the scale against Nicol in this memorable controversy.

Nicol, however, laid before this meeting a paper which, afterwards published in detail in the Journal of the Geological Society,[2] must be admitted to have really established the main facts concerning the geology of the Highlands as accepted by all geologists at the present day; though his views, as is not uncommonly the case with great and original discoveries, were met for a long time with nothing but bitter opposition or cold neglect. Permit me to state, as briefly as possible, the conclusions which Nicol, as the result of three years of patient work in the Western Highlands, was able to announce in this place, just twenty-six years ago.

1. He maintained with Macculloch and Hay Cunningham, and in opposition to the views originally propounded by Sedgwick and Murchison, that there exists in the Western Highlands an enormously thick series of red sandstones, quartzites, and limestones, which rest uncomformably upon the ancient gneisses and schists, and belong to a far older geological period than the Old Red Sandstone.

2. He showed that this series of strata really constitutes *two* distinct formations, and that the older of these, the Torridon Sandstone, consists of red sandstones and conglomerates, in which no organic remains could be detected.

3. The younger of these formations was shown by him to lie unconformably upon the Torridon Sandstone, and to consist of three members, which Nicol named the Quartzite, the Fucoid Beds, and the Limestone.[3] It is this formation which has yielded the interesting fossils of Lower Palæozoic age.

4. The apparent repetition of beds of quartzite and limestone, which was insisted upon by Murchison, was shown to be due to faulting and overthrow, and thus the

[1] *Quart. Journ. Geol. Soc.* vol. xiii. (1857), p. 36.

[2] *Quart. Journ. Geol. Soc.* vol. xvii. (1861), pp. 85–113. This paper was read on December 5, 1860; although its title is slightly different, the whole course of the argument is the same with that of the paper read here in the September of the previous year.

[3] *Quart. Journ. Geol. Soc.* vol. xvii. (1861), p. 92, &c.

'Upper Quartzite' and the 'Upper Limestone' of that author were proved to have no real existence.[1]

5. What so many authors had taken for a conformable upward succession of this older Palæozoic formation into overlying schist and gneiss, was asserted by Nicol to be an altogether fallacious appearance, due to the thrusting of the crystalline rocks over the sedimentary ones by great overthrow-faults.

6. The relations between these crystalline and sedimentary strata in the Scottish Highlands were shown to be precisely similar to those which are constantly produced by lateral pressure in all great mountain-chains, and consist of sharp foldings, inversions, and faulting on the very grandest scale. Examples of overthrow-faults, similar to those of the Scottish Highlands, were instanced by Nicol as occurring in the Alps.[2]

We cannot perhaps better illustrate the position maintained by Nicol in this remarkable paper than by quoting the following passage:—'Until some rational theory is produced of the mode in which an overlying formation, hundreds of square miles in extent and thousands of feet in thickness, can have been metamorphosed, whilst the underlying formation of equal thickness and scarcely less in extent has escaped, we shall be justified in admitting inversions and extrusion' (*i.e.*, of older masses on younger, as he explains his meaning to be) 'equal to those of the Alps.'[3]

The only serious error into which Nicol fell—and after all it is a very inconsiderable one judged in comparison with his undoubtedly great achievements—was that of attaching too much importance to the influence of igneous intrusions in connection with the tremendous inversions and overthrow-faults to which he so clearly showed that these Highland rocks have been subjected. We now know that many of these supposed intrusive masses, though really of igneous origin in all probability, were of *older* date than the Palæozoic rocks in the midst of which they lie; and that they were brought into their present positions, not by intrusion in a liquid state, but by complicated faulting. It must be remembered that these 'granulites,' as Nicol very justly called them,[4] for they present a wonderful analogy with the typical rocks of Saxony which are known by that name, have long been regarded by geologists as among the most difficult and perplexing of rocks to explain the origin of, though the recent researches of Dr. Lehmann have now done something towards the solution of the problem.

Calmly reviewing, in the light of our present knowledge, the grand work accomplished single-handed by Nicol, I have no hesitation in asserting that when this Association met here twenty-six years ago, he had already mastered the great Highland problem in all its essential details, and that his results were distinctly proclaimed during the meetings of this Section.

If, then, Nicol had so fully solved this great problem of Highland geology twenty-six years ago, how is it, may not unreasonably be asked, that we have waited so long for the justice of these views to be admitted?

A variety of circumstances have contributed to bring about this unfortunate result. Murchison was at the time too old and infirm to examine in careful detail the wild districts where these rock-masses are exhibited. Hence Nicol's oft-repeated invitations to view the sections in his company remained unheeded, and we find the great geologist of Aberdeen writing in 1866 his concluding plaintive words in this memorable discussion: 'I must express my most sincere regret that my illustrious opponent—from whom only the most thorough conviction that my views are well founded, and that the question was one on which it became a teacher of geology in Scotland to give no uncertain utterances, could have compelled me to differ—has never found it convenient to meet me again in the North. I am convinced that we agree in so many essential points, that a few hours together in the field would bring us nearer in opinion than whole volumes of controversy.'[5]

The phalanx of eminent geological authorities opposed to the views of Nicol,

[1] *Quart. Journ. Geol. Soc.* vol. xvii. (1861), pp. 98, 108, 109, &c.
[2] *Ibid.* pp. 108, 109, 110. [3] *Ibid.* p. 110.
[4] *Ibid.* p. 89. [5] *Geology of the North of Scotland*, p. 96.

including Professors Harkness, Ramsay, Archibald Geikie, and Hull, for a long time carried all before them; but it is now admitted that each of these excellent observers was deceived by having seen only portions of the evidence, and that they based their conclusions on imperfect data. Nicol, though during the later years of his life he declined unavailing controversy, still continued to study the Highlands year by year, re-examining every joint in his armour and satisfying himself of its soundness.

In the year 1877 I had an opportunity of visiting for the first time the interesting sections of Assynt and Loch Broom, in company with Dr. Taylor Smith, F.G.S., and Mr. Richard D. Oldham, now of the Geological Survey of India. Although I entered upon this task with the strongest prepossessions in favour of the Murchisonian hypothesis, yet what I saw there during several weeks of work convinced me that the theory of an 'Upper Quartzite' and an 'Upper Limestone' was altogether untenable, and that, so far as these two sections were concerned, Nicol's interpretation was undoubtedly the correct one. I was greatly impressed with the proofs of enormous folding and faulting among these Highland rocks, and when, shortly afterwards, I had an opportunity of meeting Professor Nicol in this place, and of hearing from his lips many details of his later work, I strongly urged him to republish his conclusions with the fuller illustrations and arguments which he was then so well able to supply. To all my pleadings he made but one reply: important as he knew these discoveries to be, yet in his advancing years he thought but little of the glory of them compared to their painful consequences to himself—the breach of the old friendly relations with one he, to the end, so greatly loved and honoured. He strongly deprecated at that time the re-opening of a controversy associated for him with such bitter memories; but he expressed his full conviction that when sufficiently accurate topographical maps were in existence, and the whole district should be surveyed by competent geologists, the truth of all the essential parts of his teaching would be established.[1]

Most completely have these anticipations of Nicol been fulfilled. During the last seven years many of the sections of the Western Highlands have been visited by different geologists, Dr. Hicks leading the way, and not a few papers have been published embodying the results of these new studies of some of the disputed points. Such an able review of this recent work has been lately drawn up by my friend, Professor Bonney, in his Anniversary Address to the Geological Society, that I need not go over the ground again, but will content myself by referring to that address and to two exhaustive papers read by Dr. Hicks before the Geologists' Association for full details concerning this later work. It will be seen that while new methods of study have enabled them to improve or correct Nicol's petrological nomenclature, the principal conclusions of nearly all these writers concerning the relations of the several rock-masses entirely support his views on the subject.

But very recently Nicol's work has been tested in the way which he himself so earnestly desired. Professor Lapworth, who, like Nicol, was especially prepared for the task by long and patient study of the crumpled Silurian rocks of the Borderland, taking advantage of the newly-published Ordnance maps of Sutherland, proceeded in the summer of 1882 to Eriboll, bent on the task of unravelling the complicated rocks and of mapping them upon the large scale of 6 inches to the mile. Professor Lapworth's detailed maps and sections were exhibited to the Geological Society on May 9, 1883, during the reading of a paper by Dr. Callaway, in which the views of Nicol also received a considerable amount of valuable support.

In the same year, 1883, a detachment of the Geological Survey of Scotland, under the superintendence of Messrs. B. N. Peach and J. Horne, commenced the detailed mapping of the Durness-Eriboll district. How admirably these gentlemen have performed their task we all know, and I hope that some interesting information

[1] In my two earlier papers 'On the Secondary Rocks of Scotland,' published in 1873 and 1874 respectively, I had employed the Murchisonian nomenclature for the older rocks of the Highlands whenever I had occasion to refer to them; but in the third of this series of papers, published in 1878 (*Quart. Journ. Geol. Soc.* vol. xxxiv. p. 660), I had no hesitation in abandoning this terminology for that of Nicol.

concerning their conclusions will be laid before the present meeting. In offering them—as I am sure that I am empowered by you to do—the hearty congratulations of the Geological Section of the British Association upon the auspicious commencement of this great undertaking, I cannot refrain from reminding you that, of the leaders in this important enterprise, one is the son of the discoverer of the Durness fossils, the veteran Mr. Charles Peach to whom we owe so much, while the other is a very active and efficient local secretary of this Section.

Nor should I do justice to my own sentiments on the subject, if I failed to bear tribute to the judgment displayed by the present chief of the Geological Survey in his choice of a base from which to attack this difficult problem, to his loyalty in accepting results so entirely opposed to his published opinions, and to his promptitude in making his fellow-workers in geology acquainted with these important discoveries. Unfortunately called upon while still young, and with but little of that ripe experience which he has since gained, to grapple with the most intricate of problems—problems which the most practised of field-geologists might be forgiven for failing to solve—his own judgment yielded, though not without serious misgivings,[1] when opposed to the ardent confidence of a companion and friend, whose reputation in the scientific world commanded his respect, and whose previous achievements had won his complete reliance. If, like your own Randolph at Bannockburn, he has 'lost a rose from his chaplet' at the commencement of this great Highland campaign, we are well assured that the error will be worthily repaired in its subsequent stages.

The conclusions arrived at by Nicol, by Professor Lapworth, and by the officers of the Geological Survey concerning the relations of the rock-masses in the north-west of Sutherland, are, in all their main features, absolutely identical; and the Murchisonian theory of Highland succession is now, by universal consent, abandoned.

In the second of the great controversies to which we have alluded as having occupied the attention of this Geological Section in 1859—that concerning the age and relations of the Reptiliferous Sandstone of Elgin—the combatants were found ranged in quite a different order. Nicol is seen battling shoulder to shoulder with Murchison, Ramsay, and Harkness, in favour of the *Palæozoic* age of the beds in question; while Lyell, supported by Symonds of Pendock and Moore of Bath, is as stoutly maintaining their *Secondary* age.

The finding by Mr. Patrick Duff, in the year 1852, of the little fossil lizard called *Telerpeton*, and the determination of its true nature by Mantell and Owen, constitute a discovery comparable in importance and fruitfulness to Mr. Peach's detection of the fossiliferous character of the limestone of Durness; up to that time no doubt had ever been entertained as to the 'Old Red' age of the yellow sandstone of Elgin. For bringing together the remarkable fossils of these rocks, geologists are indebted to the untiring labours of Dr. Gordon of Birnie—whom, full of years and honours, and the object of such universal respect and love as indeed make grey hairs a 'crown of glory,' we rejoice to have still in our midst. Studying Dr. Gordon's important collections, Professor Huxley was able, shortly before the previous meeting of the Association in this city, to announce that a crocodilian (*Stagonolepis*), and a second lizard of Triassic affinities (*Hyperodapedon*), existed at the period when these beds were deposited, so that even in 1859 the palæontological evidence in favour of the Mesozoic age of these rocks was admitted to be almost overwhelming.

But this evidence has been very greatly strengthened since that date; for Professor Huxley has shown that the genus *Hyperodapedon* is represented in the Trias of Warwickshire, of Devonshire, and of India. In the same reptiliferous sandstone, with its abundant footprints, there have been found the remains of a reptile which Professor Huxley permits me to state is, in his opinion, probably *Dinosaurian*. I am sure that you will all join with me in the hope that the health of the President of the Royal Society may soon be so far restored that he may be able to return to the examination of these fossil reptiles of Elgin, in the study of

[1] See *Memoirs of Sir Roderick Murchison* (1875), vol. ii. p. 238.

which some of the earliest of his great palæontological discoveries were achieved. Within the last few days the remains of another reptile, clearly referable to the *Dicynodontia* has been found; so that no less than four orders of reptiles are now known to be represented in the formation.

The manner in which the yellow sandstones, which have yielded these reptilian remains, are at many different points found associated with beds containing *Holoptychius* and other Old Red Sandstone fish, appeared to many geologists altogether inexplicable on any other hypothesis than that the strata are all of the same geological age.

In spite, however, of these appearances, and the interesting observations of Dr. Gordon and Dr. Joass on the rocks of the Tarbet peninsula, which seemed to support the hypothesis just referred to, I am able to announce that proof of the most clear and convincing character now exists of the distinction between the fish-bearing 'Old Red' and the reptiliferous 'New Red' of the neighbourhood of Elgin. In the year 1873 I showed that rocks, identical in character with the reptiliferous sandstone of Elgin, and the overlying calcareous and cherty rock of Stotfield, exist on the northern side of the Moray Firth, in the county of Sutherland, and that they there conformably underlie Rhætic and Liassic strata. Very recently Dr. Gordon has added a crowning discovery to his long list of previous ones, by detecting in the same quarry the rocks containing the reptilian and fish remains respectively. I find, however, that while the two series of beds present well-marked differences in their mineral characters, the yellow sandstones with fish remains clearly overlie the undoubted Upper Old Red, and are separated from it by a well-marked bed of conglomerate. In other quarries in the district, the manner in which these two series of strata have been thrown side by side by the action of great faults is very clearly exhibited. I hope that full details of the evidence on this interesting subject will be laid before you during the present meeting.

The facts relied upon by the Palæontologist and the Stratigraphist respectively are thus found to be no longer opposed to one another. By a complicated series of parallel faults, the Devonian and Triassic sandstones, which happen to have a general resemblance in their mineral characters, are found again and again thrown side by side with one another in the Elgin district, so that the error into which geologists fell before the discovery of the distinctive fossils of the two sets of rocks, was a very pardonable one.

A retrospect of these two controversies, now so happily laid at rest, is not, I think, without its uses for the student of Highland geology, for it may serve to furnish him with some useful warnings which are in great danger of being overlooked at the present time.

The discovery of a few fossil remains in strata where they were previously unknown, has completely revolutionized our ideas concerning the age of rock-masses of enormous extent and thickness. Resemblances in mineral character have been proved not only to have been, at their best, very unsafe guides indeed, but to have actually betrayed those who trusted in them into the most serious errors. But for the discoveries of Charles Peach on the one hand, and of Patrick Duff and Dr. Gordon on the other, geologists would probably still continue to class the sandstones of Torridon and Elgin respectively with the 'Old Red.'

But perhaps the consideration of greatest importance which is impressed upon us by this retrospect is, that in these Highland districts we must be always prepared to meet with rock-masses of very different geological ages, thrown into puzzling juxtaposition by the gigantic movements to which this part of the earth's crust has been subjected. He who enters on the study of Highland geology without being prepared to encounter at every step complicated foldings, vast dislocations, and stupendous inversions of the strata, can scarcely fail to be betrayed into the most disastrous and fatal errors.

The early history of Scotland is inextricably interwoven with that of Scandinavia. This proposition, true as it is of the insignificant periods of which human history takes cognizance, applies with even greater force to the vast epochs that fall within the ken of the geologist. To us the separation of Scotland and

Scandinavia is an event of very recent date indeed; it is not only an accident, but an uncompleted accident! The Scottish Highlands, with the Hebrides and Donegal on the one hand, with Orkney and Shetland on the other, must be regarded—to use a technical phrase—as mere 'outliers' of the Scandinavian Peninsula.

We must acknowledge, at the outset, that the study of the geological history of this Scandinavian peninsula and its outliers is a task bristling with difficulties. The problems presented to us in our Scottish Highlands are vast, complicated, and at times seemingly insoluble. But they are precisely the same problems that confront our brother geologists in Scandinavia. And if our tasks, our doubts, our perplexities are the same, we equally share in the advantages and triumphs of discovery.

The geologists of Scandinavia—and right worthy sons of Thor they are—have the advantage of possessing a territory almost limitless in its vastness, and seemingly infinite in its variety. But the very extent of their splendid country, with its sparse population and restricted means of communication, increases the difficulties of their task. 'The harvest truly is plenteous, but the labourers are few!' With our smaller area, if we cannot expect so much variety, we may hope to gain something from the number of our students and the greater accessibility of our fields of labour.

Nor would I undervalue, in this connection, the importance of the union of this country with England. I allude, of course, not to events of yesterday, like the Accession of James VI. to the English throne and the Parliamentary Act of Union, but to operations that preceded these by many millions of years! It is no small advantage that a country like Scotland, in which the rock-formations are found hopelessly crushed and crumpled together, or broken into a thousand ill-fitting fragments that seem to defy all attempts to reduce them to order, should be united to one like England, where, by comparison, all is orderly and simple, the strata lying in regular sequence like well-arranged volumes in a library, and only await the touch of the geologist's hammer to display the wealth of their fossil contents.

The great Scandinavian *massif*, with its outlying fragments, constitutes the 'basal-wreck'—to employ Darwin's expressive term—of a great Alpine chain. On other occasions I have endeavoured to show how much our study of the nature and products of volcanic action is facilitated by the existence of similar 'basal-wrecks' of volcanic mountains, like those which exist in your beautiful Western Isles. In the same way, I believe we may learn more by the study of this dissected mountain-chain, concerning the operations by which these grand features of our globe have originated, than by the most prolonged examination of the superficial characters of the Alps or the Himalayas.

Here the scalpel of denudation has laid bare the innermost recesses of the mountain-masses, and what we can only guess at in the Alps and the Himalayas, here stands in our own Highlands clearly revealed to view.

It is a well-ascertained fact that all the existing lofty mountain-chains have been formed at a very recent geological period. The reason of this it is not difficult to divine. In the higher regions of the atmosphere, the forces of denudation work so rapidly that within a very short period—geologically speaking—the vastest mountain-chain is razed to its very foundations—

> They melt like mists, the solid lands,
> Like clouds they shape themselves, and go!

It is not surprising then to find Powell and Gilbert, fresh from the study of the grand mountain-masses of the American Continent, giving expression to these thoughts in the following words: 'All large mountains are young mountains, and, from the point of view of the uniformitarian, it is equally evident that all large mountains must be growing mountains; for if the process of growth is continuous, and if a high mountain melts with exceptional rapidity before the play of the elements, it is illogical to suppose that the uprising of any mountain, which to-day is lofty, has to-day ceased.'

The Scandinavian Alps were a living and a growing mountain-chain in the far-

distant Palæozoic period. Now it is not only dead, but stretched on the dissecting-table of the geologist—its outer integuments and softer tissues stripped away, and its very skeleton bared to our view—a splendid 'subject' for the student of mountain anatomy.

One of the first to recognise this value of our Scottish Highlands to the student of Orographic Geology was the late Daniel Sharpe. He had made himself familiar with many of the characteristic details of Alpine architecture—so far as it was then understood—and was able to show that the foliated masses of our Highland districts exhibit precisely those relations which would be seen if the contorted and fan-like masses of the Alps were planed away by denudation. Nor in suggestions of this kind, as we have seen, was James Nicol far behind Sharpe; but at that time many of the most important features of mountain-structure were unrecognised or misinterpreted, and the conclusions of these geological pioneers were little more than guesses—though very valuable and suggestive guesses—after truth.

It is to our geological brethren over the Atlantic that we are especially indebted, not only for many important discoveries in the mechanics of mountain-formation, but for clearing away many of the clouds of error in which the subject had become involved. To Henry Darwin Rogers, who, after a career of valuable geological work in his native State of Pennsylvania, accepted the hospitality of this country, and spent the last decade of his useful life as Professor of Natural History and Geology in the sister university of Glasgow, must be assigned the foremost place in that school of orographic geologists which has grown up in America.

The first sketch of the important theory of mountain-building, to which Rogers and his fellow-geologists were led by the study of the Appalachian chain, was published in 1842, but it was not till 1858 that the complete evidence on which this theory was founded could be published.

The conclusion at which Rogers arrived was, briefly expressed, as follows:—The Appalachian mountains were carved by denudation out of an enormously thick mass of stratified deposits, thrown into a series of parallel wave-like folds. To the westward of the mountain range 'the crust-waves flatten out, recede from one another, and vanish into general horizontality;' but towards the heart of the mountain-mass the same flexed strata become greatly crowded together, their 'axis-planes' become more and more inclined, till at last their folds, yielding at their apices to the tremendous lateral thrust, fractures twenty to eighty miles in length, and attended with a displacement of 20,000 feet or more, were produced.

Unfortunately Rogers accompanied these just views of mountain structure with certain crude speculations and untenable hypotheses concerning the methods by which they were produced. But in the minds of other American geologists, among whom may especially be mentioned Dana, Le Conte, and Vose—the fruitful ideas of Rogers have undergone development and expansion, while they have received abundant illustration through the labours of that active band of pioneers—the United States Geological Survey—including Clarence King, Powell, Emmons, Hague, Dutton, Gilbert, and many others.

Nor have the brilliant results attained by these investigators in the New World been without their effect on the geologists of Europe. Lory, Suess, Heim, Baltzer, and others have shown that the clue to the right understanding of the structure of the Alps, which had been so diligently sought and so long missed by Von Buch and De Beaumont, by Studer and Favre, was now placed in our hands by the researches of the American geologists.

In Northern Europe, Kjerulf, Dahll, Brögger, Reusch, and other geologists have ably illustrated the same peculiarities of structure in the denuded mountain-chain near the southern extremity of which we are now assembled; and in a recent valuable and suggestive essay 'On the Secret of the Highlands' Professor Lapworth has shown how perfectly these structures are exemplified in the western district of Sutherland.

In offering a few remarks on some of the still unsolved problems of Highland geology I shall not hesitate to treat, as belonging to the same geological district, both Scandinavia and Scotland. Not only is the succession of geological deposits in the two areas almost completely identical, but the characters of the several

formations and their relations to one another in the one country are almost the exact counterpart of what they are in the other.

The problems which await solution in Scotland are the same which confront our brethren in Scandinavia; their difficulties are our difficulties, their successes our successes; if they share the benefits of our discoveries, we equally partake with them in the fruits of their achievements. Important links in the chain of geological evidence, absolutely wanting in the one area, may perchance be found in the other. Every advance, therefore, which is made in the knowledge of the rocks of the one country, must necessarily re-act upon the opinions and theories which prevail among geologists in the other.

At the base, and forming the foundation of this greatly denuded mountain-chain, there exist enormous masses of highly foliated, crystalline rocks. These, in great part at least, underlie the oldest known, fossiliferous strata, and are therefore of pre-Cambrian or Archæan age. In spite of the labours of Kjerulf, Dahll, Brögger, Reusch, Torneböhm, and many others in Scandinavia, and of Macculloch, Nicol, and their successors in this country, much still remains to be done in studying the petrographical characters and the geognostic relations of these widespread formations.

Some thirty years ago it was suggested by Sir Roderick Murchison that among these Archæan rocks there exists a 'fundamental gneiss,' a formation which is the counterpart and contemporary of the rocks in Canada, to which Sir William Logan gave the name of 'Laurentian.' Since that time other similar attempts have been made to identify portions of these Archæan rocks in the Highlands and Scandinavia with crystalline rock-masses in different parts of the New and Old World.

I confess that, speaking for myself, I am not sanguine as to the success of such endeavours. The miserable failures which we have seen to have attended similar attempts, in the case even of far less altered rocks, where identifications have been based on mineralogical resemblances only (and in connexion with which definite palæontological or stratigraphical evidence has been subsequently obtained) ought surely to teach us caution in generalising from such uncertain data. It has been argued that, where palæontological evidence is wholly wanting, and stratigraphical relations are doubtful or obscure, then we may be allowed to avail ourselves of the only data remaining to us—those derived from mineralogical resemblances. But surely, in such cases, it is wiser to admit the insufficiency of the evidence, and to say 'We do not know!' rather than to construct for ourselves a 'fool's paradise,' with a tree of pseudo-knowledge bearing the Dead-Sea fruit of a barren terminology! The impatient student may learn with the blind poet that

They also serve, who only stand and wait.

It is thought by some that the application of the microscope to the study of rock-masses may reveal peculiarities of structure that will serve as a substitute for palæontological evidence concerning the age of a rock when the latter is wanting. Greatly as I value the insight afforded to us by the microscope when it is applied to the study of the rocks, and highly as I esteem the opinions of some of those who hold these views, yet I fail to see that any such connection between the minute structure and the geological age of a rock has as yet been established.

Although the bold generalisation which sought to sweep all the crystalline rocks of our central Highlands into the great Silurian net has admittedly broken down, yet it by no means follows that the whole of these rock-masses are of Archæan age. Nicol always held that among the complicated foldings of the Highland rocks many portions of the older Palæozoic formations, in a highly altered condition, were included.[1] The same view has been persistently maintained by Dr. Hicks, to whose researches among the more ancient rock-masses of the British Isles geologists are so greatly indebted, and also by Professor Lapworth.

To the settlement of this very important question we may feel sure the effort

[1] See *Quart. Journ. Geol. Soc.* vol. xix. (1864), p. 184, and *Geology and Scenery of the North of Scotland* (1866).

of the officers of the Geological Survey will be especially directed. The geological surveyors of Scandinavia have been so fortunate as to detect, in rocks of an extremely altered character, a number of fossils sufficiently well preserved for generic and sometimes even for specific identification. Failing the occurrence of such a fortunate accident, I confess that it has always appeared to me that the disturbances to which these Highland rocks have been subjected are so extreme, and the difficulty of making out the original planes of bedding so great, that but little can be hoped for from general sections constructed to show the relations of the rocks of the Central and Southern Grampians to the fossiliferous deposits of the North-West of Sutherland.

Lying unconformably upon these Archæan crystalline rocks in our North-West Highlands we find great masses of arkose or felspathic grit, with some conglomerates, the whole of these well-stratified deposits attaining a thickness of several thousands of feet. These rocks, in their characters and their relations, so greatly resemble the 'Sparagmite Formation' of Scandinavia, that it is impossible to refrain from drawing comparisons between them. The Scandinavian formation, however, includes calcareous and slaty deposits, which are wanting in its Scottish analogue. The 'Sparagmites' of Scandinavia, as a whole, appear to underlie strata containing Cambrian (Primordial) fossils, but in the very highest portion of the 'Upper Sparagmite Formation' of Southern Norway there have been found, according to Kjerulf, specimens of *Paradoxides.*

The Scottish formation has, on the other hand, yielded no undoubted organic remains. Murchison, on the ground of its unconformable infraposition to his Silurian strata, and its resemblance to certain beds in Wales which he called Cambrian, referred it in his later years to that system. Although an identification, based on such grounds, must be admitted to be of small value indeed, yet the discovery of 'Primordial' fossils in the very similar rocks of Scandinavia may be admitted to lend it some slight support. In the present state of our knowledge, however, it is surely wiser to admit that the question of the age of these beds is still an open one, and to call it by the name suggested by Nicol—'The Torridon Sandstone.' Kjerulf believes there is evidence that the Scandinavian Sparagmite, in places, passes horizontally into true gneiss, and similar appearances are not wanting in the case of our Torridon Sandstone.

Concerning the overlying formation of quartzites and limestones, much yet remains to be made out. Nicol, Lapworth, and the officers of the Geological Survey, have shown it to be made up of three principal members—the identity of which cannot be mistaken although different names have been assigned to them. While Nicol estimated the total thickness of this formation at from 300 to 800 feet, however, and Lapworth places it at the smaller of these amounts, the officers of the Survey believe it to be no less than 2,000 feet thick.

Even greater uncertainty still exists as to the exact geological age of this important formation. Murchison, who in his later years made 'Silurian' a mere synonym for Lower Palæozoic, was no doubt right in regarding these rocks as being of that age. I have no intention of attempting to flog that dead horse—the controversy concerning the names which should be applied to the great systems containing the three faunas which Barrande so well showed to be present in the Lower Palæozoic rocks. That controversy, commencing, it must be confessed, with some tragic elements, has long since passed into the sphere of comedy, and now bids fair, if still persisted in, to degenerate into farce. Little, if anything, has been added to the work of Salter in connection with these fossils of the Durness limestone. With their abundance of that remarkable and aberrant mollusc, *Maclurea*, they can be paralleled with no other British or even European deposit, unless it be the Stinchar limestone of the Girvan district. Salter thought that this remarkable Scotch formation had its nearest analogues in the Calciferous sandstone and the Chazy limestone of North America. As those rocks contain 'Primordial' forms of Trilobites, they must probably be regarded as either of Cambrian age, or as constituting a link between the rocks containing Barrande's first and second faunas respectively. Under these circumstances, it is a piece of welcome intelligence that the officers of the Geological Survey have succeeded in obtaining a rich and

varied collection of organic remains from the beds of Sutherland; and the results of the examination and discussion of these fossils will be awaited by all geologists with the greatest interest.

Whether, as in case of Scandinavia, other fossiliferous deposits of Silurian age will be found to be represented in a highly metamorphosed condition in our Scottish Highlands, remains to be discovered. There is such a perfect parallelism between the several members of the Silurian in Scania and in the Scottish Borderland, so well shown by the researches of Linnarson and Lapworth, that, as Nicol always anticipated, we may not improbably find a portion of the rocks of the Highlands to be altered forms of those of the Borderland.

Since the last meeting of the British Association in the Highlands, much progress has been made in the study of that pre-eminently British formation—the Old Red Sandstone. Dr. Archibald Geikie has thrown much new light, by his valuable researches, on the relations of the several members of the vast series of deposits which go by that name; while Dr. Traquair, bringing to bear on the subject great anatomical knowledge, has re-examined the collections of fossil-fish made by that indefatigable explorer, Hugh Miller. The Old Red Sandstone is the only great system of strata which we possess, while it is either wholly absent, or very imperfectly represented, in Scandinavia.

In the year 1876, I was able to announce that a vestige—a small but highly interesting vestige—of the great Carboniferous system exists within the limits of the Scottish Highlands. Well do I recall the deep, the ineffaceable impression made upon my mind when, standing at the Innimore of Ardtornish, I beheld for the first time this relic of a great formation, preserved by such a wonderful series of accidents. What the inscribed stone of Rosetta or the papyri of Herculaneum are to the archæologist, this little patch of sandstone is to the geologist. Overwhelmed by successive lava-streams that were piled upon one another to the depth of many hundreds of feet, and then carried down by a fault which buried it at least two thousand feet in the bowels of the earth, this fragment has remained while every other trace of the formation has been swept from the Highlands by the besom of denudation.

Highly interesting and important in these northern areas are the Mesozoic deposits, which in places attain a vertical thickness of several miles, and which must have originally covered enormous tracts of country. Now, judged by that very fallacious test, the space which they cover upon our geological maps, they appear in the Scottish Highlands to be absolutely insignificant.

The correspondence in characters between the several Secondary formations on the two sides of the North Sea is of the most striking kind. I have had the good fortune to study the Secondary rocks of Scania under the guidance and with the assistance of Professor Lundgren, of the University of Lund, who has made so many important discoveries in connection with them. While doing so, I have again and again felt almost constrained to pause and rub my eyes, to convince myself that I was not back again in Scotland—so complete is the correspondence between the mineral characters, the fossils, and the geognostic relations of these strata in the two areas.

The Triassic rocks of Scandinavia, consisting of variegated sandstones and conglomerates, containing much calcareous material, are absolutely undistinguishable from those of the Western Highlands. In both countries the thickness of the deposits of this age varies within very short distances, their development being local and inconstant. The formation which in places exceeds a thousand feet in thickness, at other points is reduced to an insignificant band of conglomerate. On the eastern flank of our Highlands, yellow sandstones belonging to this formation have yielded to Mr. Duff, Dr. Gordon, Mr. Grant, and others that interesting series of reptilian remains which, in the hands of Professor Huxley, have been made to throw such important light on the forms of life which existed at that remote geological period. In the very similar deposits which occur in Scandinavia, however, reptilian remains have not as yet been obtained. The abundance and variety in form and size of the footprints which occur in our Scottish rocks of this age indicate the richness of the vertebrate fauna which must have existed at that distant epoch.

On both sides of the North Sea, the Triassic rocks are found passing up insensibly into the great formation known as the Rhætic and Infralias—a formation imperfectly represented in England and Central Europe by a few thin and insignificant strata, but in our Highland districts attaining a vast thickness and exhibiting a magnificent development. This system of strata consists of alternation of marine and estuarine deposits, the latter containing in both areas thin seams of coal. In Scania, the working of the coal and fire-clays of these deposits has brought to light vast numbers of fossil plants, which have been so well described by Nathorst. Several very distinct floras, occurring at different horizons, have been made out, and the relations of the beds containing these floras to one another, and to the marine strata with which they are intercalated, have been clearly demonstrated by the researches of Hébert, Erdmann, and Lundgren. That similar rich stores of fossil plants would reward a search as skilful and persevering as that made by our Scandinavian brethren, if carried on in the equivalent strata of Scotland, there can be little doubt.

The whole of the vast Jurassic system in these northern latitudes, attaining a thickness of 3,000 or 4,000 feet, appears to be similarly made up of alternations of marine and estuarine strata. Time would fail me to indicate even in the briefest manner the numerous problems of the highest interest suggested by the study of these vast deposits. At many different horizons, beds of coal and the relics of a rich terrestrial vegetation abound. Most of these await careful study and description. So far as they are yet known, the Ferns, the Cycads, and the Conifers of the Jurassic rocks of the Highlands present wonderful resemblances with those described by Heer from strata of the same age in Norway, in Russia, in Siberia, and even far away in the Arctic regions. The marine forms occurring in the associated strata seem to indicate that they belong to an ancient life-province, distinct from those in which the Jurassic rocks of Central and of Southern Europe were deposited. In the Upper Jurassic, so well represented in Sutherland by strata not less than 1,000 feet in thickness, we find evidence of the existence of mighty rivers, the banks of which, though clothed with tree-ferns, cycads, and gigantic pines, yet at certain seasons must have borne down ice-buoyed blocks of vast dimensions.

That the succeeding Neocomian period was for Scandinavia and Scotland an epoch of elevation and of the prevalence of terrestrial conditions is indicated by the total absence of any trace of marine deposits of this age, no less than by the enormous denudation which can be shown to have followed the Jurassic and preceded the Cretaceous period. Our now ruined mountain-chain then probably formed the lofty watershed of a great continent, through which flowed the mighty rivers that formed the deltas known as the English and German Wealdens.

How powerful and prolonged were the agencies of sub-aerial waste during this period is shown by the fact that the relics of the Cretaceous formation are found resting in turn on every member of the Jurassic, the Rhætic, the Trias, and all the different Palæozoic and Archæan rocks. A great portion, indeed, of the thick and widespread Rhætic and Jurassic strata seems to have been removed by denudation before the commencement of the Cretaceous period.

That thick strata of chalk once covered large areas of the Scottish Highlands and of Scandinavia we have the clearest proofs. In Scania and the adjoining parts of Denmark deposits of this age are found let down by tremendous faults, and these include even younger members of the series than are anywhere found in England. In the West of Scotland I have shown that thin deposits of Cretaceous age, preserved to us by a wonderful series of accidents, still survive the tremendous denudation of the Tertiary periods. It is true that in Scandinavia and Scotland alike, the chalk alternates with sandstones and even with strata of estuarine origin, but the pure foraminiferal rock that occurs in both areas could have been formed in no very shallow sea. That before the commencement of the great Tertiary denudation large areas, in Scandinavia and Scotland alike, must have been swathed in winding sheets of chalky rock there cannot be the smallest doubt. That considerable portions of these winding-sheets remained to so late a period as the glacial is shown by the fact that the indestructible flints of the chalk

with the rocks and fossils of the upper greensand abound in your boulder-clays of Aberdeenshire and Banffshire.

Of the vast periods of the Tertiary we have left to us, either in the Highlands or Scandinavia, but few and insignificant relics in the form of stratified deposits. In our beautiful Western Isles and in Antrim the lava poured out in successive streams, during enormous periods of time, from the lofty volcanic cones of the earlier Tertiary epoch, has here and there buried patches of lake-mud, or river-gravel, or ancient soils. But everywhere, alike in the Highlands and in Scandinavia, we behold the most impressive evidences of the sub-aerial waste, and of the elevation that promoted this waste during the Tertiary epoch. Among such evidences we may reckon the circumstance that all traces of the vast deposits of the Secondary periods have been relentlessly stripped away from the country, except where buried deeply by gigantic earth-throes, or sealed up under massive lava-streams.

Down to post-glacial times Scotland, and what are now its outlying islands, remained united with Scandinavia. I need not remind you how, during the glacial period, they were the scene of a similar succession of events; while from their then far more elevated mountain-summits streams of glacier-ice flowed down and relieved the mantle of snow which enveloped them.

But at a very recent geological period, and indeed since the appearance of man in this part of our globe, the separation of the two areas, so long united, was brought about. In the district now constituting the North Sea, which separates the two countries, great faults, originating in the Tertiary epoch, appear to have let down wide tracts of the softer Secondary strata among the harder crystalline rock-masses. The numerous changes of level, of which we find such abundant evidence around the shores of this sea, facilitated the wearing away of the whole of these softer Secondary deposits, except the slight fringes that remain along the shores of Sutherland, Ross, and Cromarty, on the one hand, and the isolated patches forming Scania, Jutland, and the surrounding islands on the other. Little could the Vikings, as they sailed over this shallow sea, have imagined that their predecessors in these regions were able to roam on foot from Norroway to Suderey!

It is almost impossible to over-estimate the effects produced by the several denudations to which Scandinavia and the Scottish Highlands have been successively subjected. In that which occurred during the later Tertiary periods, almost every portion of the non-crystalline rocks that rose above the sea-level was either entirely removed or converted into level plains, which, covered with drift deposits, now form districts like Scania and Denmark. Where, as in the great central valley of Scotland, hard volcanic masses are associated with the softer sedimentary rocks, the former are left rising as picturesque crags, standing boldly up above the general level, while the latter are worn down and buried under drift. In the west of Scotland a chain of volcanic mountains, with summits towering to the height of from ten to fifteen thousand feet, have been reduced by this same denudation to basal-wrecks, the highest portions of which attain to but little more than 3,000 feet above the sea-level!

During the great elevation and denudation which marked the Neocomian period, thousands of feet of strata must have been removed over wide areas, as is proved by the wonderful overlap of the Cretaceous beds on all the older strata.

Of the enormous sub-aerial waste which went on in these Northern Alps during the Newer Palæozoic periods we have impressive evidence in the vast masses of the Old Red Sandstone and Carboniferous rocks—themselves only a series of fragments that have survived the later denudations—for these rocks are built up of the materials derived from our Northern Alps.

The Torridon Sandstone is the monument, and a very striking monument too, of another and still earlier period of enormous denudation. The thousands of feet of conglomerate and sandstone of which it is made up consist of the disintegrated crystals of granites and gneisses that have been swept away.

When we penetrate towards the axis of this eroded mountain-chain, the proofs

of the magnitude of these denudations become even more striking and impressive. Here we see, towering aloft, the ruined buttresses of vast rocky arches, that when complete must have risen miles above the present surface; there we find, lying side by side, rock-masses that could only have been brought together by displacements of tens of thousands of feet; yet so complete has been the planing down of the surface since, that it requires the most careful study even to detect the almost obliterated traces of these grand movements. The Alps and the Himalayas, during their elevation, have suffered enormous waste and denudation; but if the elevation were to cease and the waste to go on till these magnificent mountain-chains were reduced to masses of diminutive peaks, ranging from 2,000 to 8,000 feet in height, we should then have the counterpart of this stupendous ruin of the mountain-chain of the north.

The history of the series of successive movements to which the rock-masses of our Highlands have been subjected is one well worthy of the most attentive study. When the evidence bearing upon the subject is carefully sifted and weighed, we become convinced of the fact that many of these movements—including some on a prodigious scale—must have taken place during what we are commonly accustomed to regard as comparatively recent geological periods.

On the eastern coast of Sutherland, a mass of Secondary rocks, including several thousands of feet of Triassic, Rhætic, and Jurassic strata, has been let down by a gigantic fault, so as to be placed in juxtaposition with the Old Red Sandstone and the crystalline rocks. Now, taking the very lowest estimates of the thicknesses of the several strata affected, the vertical 'throw' of this fault must have exceeded a mile! It may not improbably, indeed, have been at least double or treble that amount! Yet this great dislocation was certainly produced at a later date than the Upper-Jurassic period, for rocks of that age are found to be affected by it.

Along the coasts of the Black Isle, strata of Middle and Upper Jurassic age are similarly found faulted against the 'Old Red' and the crystalline rocks.

On the other side of the North Sea, in Ando, one of the Lofoten Isles, a patch of Lower-Oolite strata, consisting of marine and estuarine strata, and including beds of coal like that of Brora, is found let down by gigantic faults into the very heart of the crystalline rocks of the district. In Scania, the whole of the Secondary rock-masses owe their preservation in the same way to a plexus of tremendous faults, by which they have been entangled among the harder rocks. These faults have affected not only the Jurassic strata, but even the very youngest members of the Cretaceous series.

Nor are we without evidence that some of the great faults are of post-Cretaceous age, in this country, for in the Western Highlands displacements of several thousands of feet have been detected, which affect not only the Upper Cretaceous, but also the Older Tertiary rocks.

The effects produced by these great dislocations, which have a generally parallel direction in our Highlands, from north-east to south-west, are of the most startling character. Great strips of Triassic and Old-Red-Sandstone strata, like those of Elgin, and Turriff, and Tomintoul, and of the line of the Caledonian Canal, are found let down among the crystalline rocks by these gigantic faults.

The great central valley of Scotland itself consists of masses of Newer Palæozoic strata, faulted down between the harder Archæan and Lower Palæozoic rocks which form the Highlands on the one hand, and the Borderland on the other.

The evidences of the existence of these great faults were collected by many of the older Scottish geologists, like Landale, Bald, Chalmers, Milne-Home, and Nicol; and the accurate mapping of the country by the officers of the Geological Survey has, on the whole, tended to confirm their results. With regard to the age of these great dislocations of Central Scotland, it can only be *certainly* affirmed that they are of more recent date than the youngest Carboniferous strata; but I have long believed that, like many similar dislocations both in our own Highlands and in Scandinavia, they are really post-Cretaceous.

Less difficulty perhaps will be found in accepting this apparently startling

conclusion, when we remember that a complicated series of fractures injected by the lavas of the Great Tertiary volcanic foci of the West, extend right across the Highlands, the central valley, and the Borderlands of Scotland, and even traverse the whole series of the Secondary rocks in the North of England.

The indications of the tremendous manifestations of subterranean energy, to which these great dislocations owe their origin, are sometimes of a very striking kind. For hundreds of yards on either side of the faults, the two sets of strata are found bent and crumpled, and not unfrequently crushed into the finest dust ('fault-rock'). In the case of the great Sutherland-fault, to which I have previously alluded, we have a beautiful illustration of the way in which mineral veins may originate along such lines of fissure, for in the interstices of the granite of the Ord, where it has been broken up along this certainly post-Jurassic, and probably Tertiary fault, fluor-spar and pyrites have been deposited in large quantities.

It is impossible to study the tremendous movements and dislocations, and the enormous amount of denudation which have taken place in the Highlands and surrounding districts during Tertiary times, without being convinced that all the existing surface-features of the country must date from a comparatively recent period. The vast movements which have placed soft and hard masses in opposition along certain parallel lines—generally ranging in a north-east and south-west direction—and the denudation which has worn away the former, while it has left the latter standing in relief, must, I believe, both be referred to the Tertiary period; though the disposition of rock-masses brought about by earlier movements would of course exercise a certain though subordinate influence in producing the existing forms of the surface of the country.

At the close of the Jurassic period, and before the commencement of the Cretaceous, during the vast epoch marked by the deposition of the Neocomian of Southern Europe, a series of disturbances similar to those of the Tertiary, and scarcely inferior in their consequences, can be shown to have taken place.

If the movements of the Scandinavian and Scottish rock-masses, which took place in the Tertiary and Mesozoic periods respectively, were so startling in their magnitude and so vast in their effects, what shall we say concerning those far greater disturbances which affected the same area towards the close of the Older Palæozoic, and the beginning of the Newer Palæozoic, when this Northern Alps was still a living and growing mountain-chain?

These movements, in which both the Archæan and the Older-Palæozoic rocks are found to be involved, have resulted in the production, through enormous lateral pressure, of those reversed faults, caused by the disruption along their axial planes of greatly inclined and compressed folds as so well described by Rogers.

Dr. Archibald Geikie assures us that the studies of the geological surveyors in North-west Sutherland lead to the conclusion that certain masses of rock have thus been carried almost horizontally over others, along these 'thrust-planes' for a distance of at least ten miles. As the result of these tremendous lateral compressions, thin beds of limestone and quartzite, which have sufficiently definite characters to permit of their recognition, may be seen in Assynt, and in other parts of the Western Highlands, to be so repeated again and again by crumpling and faulting, that they have been regarded as deposits of enormous thickness; while, on the other hand, massive formations have been crushed and rolled out, thereby acquiring a laminated structure like so much pie-crust. Great portions of rock-masses, which, like the much-discussed 'Logan-rock,' have been nipped between gigantic faults, show evidence under the microscope of having been crushed to powder and subsequently reconsolidated, while the surfaces of the 'thrust-planes' sometimes exhibit the phenomena known as 'slickensides' on the most gigantic scale.

As we pass away from the central axis of this old mountain-chain, however, these complicated puckerings and dislocations pass gradually into more ordinary folds and faults, just as is the case with the Appalachians. The oft-repeated undulations of the Lower Palæozoic strata of the Borderland, so admirably described by Professor Lapworth, bear the same relation to the far more involved disturbances of rocks of the same age in the Highlands, which the foldings of the

strata in the Jura do to the intense crumplings of those of the Alps; and these in turn pass insensibly into the slightly undulating or horizontal strata of the southern half of this island.

We may perhaps add another comparison between the existing mountain-chain of Southern Europe and the 'basal wreck' of Northern Europe, one which I find has been already suggested by Professor Bonney. The Miocene Conglomerates, which in the Rigi and other flanking mountain masses of the Alpine chain are found piled to the depth of many thousands of feet, seem to be exactly represented in its prototype by the vast masses of the 'Old-Red' Conglomerate.

Vast as were the three series of movements to which I have been referring, I believe that the Scandinavian and Highland rocks bear the impress of a still grander series of disturbances than either of these—one at the same time of older date and far more universal in its effects.

Many writers have treated of the great divisional planes, almost everywhere conspicuous in the Highland rock-masses, as being necessarily coincident with planes of sedimentation. It is manifest, indeed, that the tracing of sequences and unconformities among such rocks must proceed upon the assumption that the planes of foliation and stratification *are* coincident. Murchison and Geikie so fully recognised the fact that this proposition lay at the very root of their arguments concerning a Highland succession, that they added a supplement to their paper to illustrate and enforce it.

It must not be forgotten, however, that the truth of this proposition has not only been doubted, but has been stoutly contested by many of the most profound thinkers on geological questions.

As long ago as 1822, Professor Henslow, in a very remarkable paper, showed that the rocks of Anglesea are traversed by a system of divisional planes, which intersect the bedding at a very high angle, and must have been produced long subsequently to the latter; and in 1835 Professor Sedgwick extended the observations and enforced the arguments of Henslow.

At an even earlier date, Poulett Scrope had shown, by his study of viscous lavas, that the planes along which crystalline action takes place are determined by pressure and strain; and he insisted that the foliation of metamorphic masses was a phenomenon strictly analogous to the banding of rhyolitic lavas.

Charles Darwin, the pupil of Henslow and the friend of Poulett Scrope—whose labours in the geological field would perhaps have met with fuller recognition had they not been overshadowed by his still greater achievements in the world of biological thought—strongly maintained the truth of these views. He added the important observation that, in the South-American continent, the planes of foliation are seen everywhere, over enormous areas, to be parallel to those of cleavage; and that these latter are of secondary origin and due to lateral pressure, the observations of Sharpe and the experiments of Sorby have convincingly demonstrated.

That the schists and gneisses of our Highlands and of Scandinavia have resulted from crystallising forces, acting upon strata of sandstone, clay and limestone, or upon igneous materials constituting lava-currents, or intrusive sheets, dykes, and bosses, I see every reason for believing. That these re-crystallised and highly-foliated masses in the great majority of cases maintain their original positions and relations, or indeed anything approaching their original positions and relations, I greatly doubt; and my doubt on this point has increased the more I have studied the Highland rocks.

Thin bands of quartzite may be the rolled-out representatives of massive beds of sandstone or conglomerate; wide-spreading schists may consist of the crystallised materials of clays and shales, crumpled, pleated, and kneaded together in endless convolutions; vast sheets of gneiss may have originally been intrusive bosses of granite or thick strata of arkose. How, then, are we to apply the ordinary principles that regulate questions concerning dip and strike, and unconformity in the case of sedimentary deposits, to highly-altered rocks like these?

The observations of Jukes, Allport, and Phillips on some of the simpler and more easily explicable examples of the production of foliation in rocks require to be cautiously extended, by patient study in the field and in the laboratory, to cases of

a more complex and difficult character. Especially in this connection do we welcome such contributions to our knowledge as that made by Mr. Teall in his description of the remarkable foliated dyke of Scourie.

Very significant indeed is the fact that the phenomenon of foliation appears to be confined to regions which have been the scene of the most violent subterranean movement and disturbance. That solid rock-masses, subjected to the tremendous earth-strains to which they are liable during mountain-making, are capable of internal movement and flow—like the ice of a glacier—we have the clearest evidence. Many illustrations might be adduced in support of the view that crystallisation is influenced and controlled by mechanical forces—pressures, stresses, and strains. May it not also be true, as long ago suggested by Vose, that the heat which must be generated in the great shearing movements taking place in rocks have also had much to do in giving rise to that re-crystallisation which is the essence of foliation? Rock-masses, in the throes of mountain-birth, have, like glaciers, behaved substantially as viscous bodies; may not the former have undergone molecular changes analogous to regelation in the latter?

That many of the stupendous earth-movements which produced the foliation of the rocks of Scandinavia and the Scottish Highlands must be referred to Archæan times, there is not the smallest room for doubt. That similar effects have resulted from the same agencies during subsequent periods, our fellow-geologists in Scandinavia believe they have found incontrovertible proof. For my own part I look forward confidently to the establishment of the same conclusion from the study of our own Highland rocks.

But here I am conscious that I am venturing on topics upon which great and allowable differences of opinion still exist. The debates in this Geological Section during the first meeting of the British Association in Aberdeen ought, I think, to have marked the practical close of one great series of controversies. The discussions of the present meeting will, I trust, result in the recognition and clear statement of a number of other equally important problems of Highland geology which still await solution. And I am sanguine enough to hope that when this Association next gathers here, my successor in this chair will have to congratulate his audience upon a very brilliant retrospect of work actually accomplished in the interval.

I am encouraged in this optimism by the fact that in the period which has elapsed since our last meeting here, great and important improvements have been made in the methods of geological investigation. We have seen how the discovery of a few fragmentary shells in the limestone of Durness, and of sundry casts of bones in the sandstone of Elgin, have been the means of profoundly modifying our ideas concerning the age of vast tracts of rock in the Highlands. The development of modern methods of petrographical research is destined, I believe, to lead to a similar revolutionizing of our views concerning the wonderful series of changes which have taken place within rock-masses, subsequently to their original accumulation.

Especially does the application of the microscope to the study of rocks, when employed in due subordination to, and illustration of, work done in the field, promise to be the source of valuable and fruitful discoveries in the field of Highland geology.

In connection with this subject, I cannot refrain from reminding you that while the initiative in the application of the palæontological method of research was taken by an English land-surveyor, we are indebted to a Scotchman in an equally lowly station of life, for overcoming some of the first difficulties in connection with petrographical study. Many microscopists had employed their instruments, and sometimes with useful results, in the study of the powders and the polished surfaces of rocks; but it is to William Nicol of Edinburgh, the inventor of the well-known polarising prism which bears his name, that we owe the discovery of the method of preparing transparent sections of fossils, crystals, and rocks, whereby their internal structure may be examined by transmitted light. Nicol bequeathed his preparations to his friend Alexander Bryson, and some of them are now preserved in the British Museum. It is interesting, too, to recall the circumstance that it was a thin section of the granite of Aberdeen in the collection of Bryson which exhibited to

Sorby that wondrous assemblage of minute cavities containing liquids, and led him, shortly before our previous meeting here, to write his paper 'On the Microscopical study of Crystals, indicating the origin of Minerals and Rocks'—a paper which has indeed proved epoch-making in the history of geology.

Before concluding the remarks which by your kindness I have been permitted to offer you to-day, I cannot forbear from indulging in a pleasant reminiscence of a personal character. Nearly fifteen years have passed away since I first visited the Highlands for the purpose of geological study; it was at that time I first found myself at liberty to put into practice a scheme cherished by me from boyhood, that of studying those Secondary rocks and fossils of the Highlands, among which such valuable pioneer work had been done by John Macculloch, Roderick Murchison, and Hugh Miller. I had endeavoured to prepare myself for a somewhat difficult task, by a training partly unofficial and partly official—I will not employ the terms 'amateur' and 'professional,' for of late they have been so sadly misused—but when I came a stranger among you, I could not have deserved, and I certainly did not anticipate, that cordial welcome, that kindly aid and that generous appreciation, of which I accept my position here to-day as the crowning manifestation.

While I continue to occupy myself with the glorious problems of Highland geology—and hitherto I have found that each difficulty surmounted has resulted, like the sown teeth of the slaughtered dragon, in a plentiful crop of new ones—the many acts of kindness of my numerous friends here can never cease to be present in my mind. For not only am I indebted to those who, like your own Dr. Gordon of Birnie and Dr. Joass of Golspie, have been able out of the stores of their knowledge to furnish me with 'things new and old,' and who have been unfailing in their aid and sympathy, but to those also who have pitied, but nevertheless helped, the 'daft callant that speers after the chucky stanes.'

I know of no higher pleasure than that which the geologist experiences in visiting regions of great scientific interest which are new to him, and of grasping the hands of fellow-workers, whose labours and teachings he has learned to admire and to appreciate. Whatever may be my lot in this way in future years, however rich the country visited may be in objects of profound instructiveness or of surpassing interest, I can anticipate or desire nothing more valuable than the lessons, or kinder than the reception which I have met with here.

'I'll ask na mair, when I get there,
Than just a *Hielan* welcome.'

The following Reports and Papers were read:—

2. *Fifth Report on the Earthquake Phenomena of Japan.*
See Reports, p. 362.

---

3. *On some recent Earthquakes on the Durham Coast, and their probable cause. By* Professor G. A. Lebour, *M.A., F.G.S.*

Since the end of 1883 up to the present time the inhabitants of certain portions of the town of Sunderland have been much disturbed by a series of small but distinctly sensible earthquakes, which have caused considerable discussion in the local press and elsewhere. These shocks were chiefly felt in that quarter of the town known as the Tunstall Road, but were not absolutely limited to that locality. They were accompanied by rumblings—sometimes dull but often loud—by the rattling of crockery and furniture, and frequently by very distinct shakes of the entire framework of buildings. Often the shocks have, at night, waked up and terrified the sleeping inhabitants.

The probable origin of these disturbances has naturally been much canvassed, and blasting in quarries, shot-firing in collieries, and the passing of railway trains have in turn been accused of causing them, and, on examination, have been found 'not guilty.' At the present time there is no doubt whatever that the shocks are due to some *natural* cause. As to what that natural cause may be there is, perhaps, room for difference of opinion.

My friend Mr. M. Walton Brown, of the Coal Trade Offices at Newcastle-upon-Tyne, in a paper read in 1884 before the North of England Institute of Mining and Mechanical Engineers, refers to the Sunderland shocks as being genuine earth-tremors, but I think that their extremely local character—setting aside many other points inconsistent with this view of their origin—is conclusive against this being so.

In another paper, read, at the same time as Mr. Walton Brown's, before the same Institute, I brought forward a number of facts tending to connect the phenomena above referred to with certain peculiarities in the geological structure of the district. Since that time, the shocks having continued more or less continuously, and evidence of all kinds with regard to them having accumulated, I wish to lay my more mature views on the subject before Section C, in the hope that members in discussing them may help to elicit the truth.

Sunderland stands upon the Permian Magnesian Limestone, of which there is from 300 to 400 feet beneath the town. This rock is riddled with cavities of every size and shape. The smaller ones give a vesicular aspect to the stone in many places, but the larger ones are often true caverns, due to the combined action of mechanical and chemical agencies. Many of them may be accounted for by noting how frequently masses, both large and small, and of all shapes of soft pulverulent matter occur in the midst of the most compact and hard portions of the limestone. How easily such soft, incoherent, earthy rock, or 'marl,' as it is called locally, can be removed by the merest percolation of rain-water where there is an outlet needs no proof, and that caverns would result and have resulted from such removal is clear. This action is indeed chiefly mechanical, but there is also going on at the same time a very considerable destruction or removal of rock by the ordinary chemical action of rain-water on limestone. I have shown elsewhere that every thousand gallons of Sunderland water, pumped up and ultimately thrown into the sea, represents one pound of stone abstracted. In each year the Water Company robs the Magnesian Limestone in this manner of about forty cubic yards of rock, and, of course, much more is carried off annually by natural channels. How large some of the cavities are which form water-cisterns in this rock may be gathered from the fact that when, in sinking a shaft at Whitburn Colliery in 1874, one of them was unfortunately tapped, it yielded 11,612 gallons of water per minute for a month.

The rock then immediately underlying Sunderland is a mass of calcareous stone mostly hard and compact, but cellular in places and earthy and friable in others, often cavernous on a large scale, full of water, and through its action continually parting with its substance, and *thus enlarging the cavities within it.*

Under conditions such as these, it follows necessarily that the vaults of cavities must, from time to time, give way, and, in collapsing, produce concussions accompanied by noise, but limited in the area over which their effects would be felt. In short, it seems to me that we have in such natural stone-falls at moderate depths a sufficient explanation of the Sunderland earth-shocks.

In the paper before alluded to I pointed out that this theory explains equally well all the facts connected with the singular fissures full of breccia ('breccia-gashes'), which are common in the Magnesian Limestone of Durham, and have been a standing puzzle hitherto to Lyell, Sedgwick, and all the geologists who have published accounts of the magnificent sections exhibited along the coast between South Shields and Sunderland.

Quite recently very similar shocks have been felt, as I am informed, in the neighbourhood of Middlesborough, where it is probable that they are due to the withdrawal of rock-salt, which has been going on there of late years only. In this case the depth at which the cavities are being formed and rock-collapses are, as I

believe, taking place is much greater than in the Sunderland case, the borings for salt being from 1000 to 1200 feet deep.

I will conclude with a quotation from my paper on the Breccia-Gashes [1] (p. 174): 'The forms of these gashes, which are gullet-shaped and tapering downwards, unlike the sea-caves; the breccia with which they are filled, the matter with which the fragments are cemented, the half-broken beds which so often bridge over the upper portions of the fissures, and the unbroken beds immediately above and below them, which would be inconceivable had the fissures and their infillings been due to real earthquakes—all these things are necessary accompaniments of the rock-collapses which, it has been shown, must in time past have happened frequently, are happening still, and must happen more and more frequently in the future.'

---

4. *Notice of an Outline Geological Map of Lower Egypt, Arabia Petræa, and Palestine. By* Professor EDWARD HULL, *LL.D., F.R.S., F.G.S.*

The map exhibited was enlarged from that which accompanies the author's book 'Mount Seir, Sinai, and Western Palestine,' giving a narrative of the expedition sent out into these countries by the Palestine Exploration Society in 1883–84. It embraces a region extending from the valley of the Nile on the west to the table-land of Edom (Mount Seir) and Moab, including the Jordan-Arabah Valley, and the mountains of Sinai. Its northern limit is the Lebanon. The following formations and divisions are represented:—

RECENT.	1. Sandhills of Lower Egypt, the coast of Palestine, and Arabah Valley. 2. Alluvial Deposits of the Nile, the Ghor, and Jordan Valley. 3. Gravel of the Wâdy el Arabah.
RECENT AND POST-PLIOCENE TO PLIOCENE.	1. Raised Beaches bordering the Gulfs of Suez and Akabah, the Isthmus of Suez, and borders of Palestine. 2. Ancient Deposits of the Salt Sea (Dead Sea). 3. Old Lake-beds of the Sinaitic Peninsula and Arabah Valley.
EOCENE TO CRETACEOUS.	1. *Upper Eocene.* Calcareous Sandstone of Phillistia. 2. *Middle and Lower Eocene.* Nummulite Limestone. 3. *Upper Cretaceous.* Cretaceous Limestone. 4. *Cenomanian.* Nubian Sandstone.
LOWER CARBONIFEROUS.	1. Limestone of Wâdy Nasb. 2. Desert Sandstone and Conglomerate.
METAMORPHIC ROCKS. (Archæan ?)	Granite, Gneiss, and various kinds of Schist.
MODERN VOLCANIC ROCKS.	Basalt, Dolerite, &c.
ANCIENT VOLCANIC OR PLUTONIC ROCKS.	Granite, Porphyry, Felstone, Diorite, &c. Beds of Tuff and Agglomerate of Wâdy Haroun and Jebel esh Shomrah.

The main lines of fault and dip of the strata are also indicated.

As an outline of the scientific results which were arrived at by the members of the expedition, and which are represented on the map, had already been communicated to the Association,[2] it was not considered necessary to repeat them here, but the author wished to add that a topographical and geological map of the Arabah

[1] See *Trans. N. E. Inst. Min. Eng.* vol. xxxii. (1884)
[2] *Rep. Brit. Assoc.* (Montreal Meeting, 1884), Transactions of Sections C and E.

Valley on a scale of about six miles to one inch was in preparation, and would accompany the Geological Memoir now in the press for the Palestine Exploration Society. The topographical survey had been made by Major Kitchener, R.E., and Mr. John Armstrong (formerly sergeant-major, R.E.), and the geological details had been inserted by the author. In addition to these, several longitudinal geological sections, illustrating the structure of various parts of this region, and numerous drawings would accompany the Memoir.

5. *On the Occurrence of Lower Old Red Conglomerate in the Promontory of the Fanad, North Donegal. By* Professor EDWARD HULL, *LL.D., F.R.S., F.G.S.*

The district in which the Old Red Conglomerate occurs is formed of ridges and valleys of metamorphic rocks, consisting of beds of quartzite, schist, crystalline limestone, and trap, chiefly diorite. It lies between Lough Swilly and Mulroy Bay, and is washed on the north by the waters of the Atlantic. The remarkable tract of the Old Red Conglomerate, recently discovered by the officers of the Geological Survey, is far remote from any mass of the same formation, and it is unrepresented on any geological map hitherto published.

The beds consist of red and purple sandstone and conglomerate, made up chiefly of quartzite pebbles and blocks, but also containing others of limestone and trap; all derived from the surrounding metamorphic series. They occupy an area of over two miles in length and half a mile across, extending along the northern base of Knock Alla, a ridge of quartzite which traverses the promontory from side to side. The beds dip towards the base of the mountain, against which they are let down by a large fault, and they terminate along their northern edge by an unconformable superposition on beds of quartzite and limestone. They reach a total thickness of about 800 feet.

From the position of these beds it becomes evident that they are unconnected with any of the recognised basins of Lower Old Red Sandstone, either in Scotland or Ireland, and may, therefore, be regarded as having been formed in an isolated basin. The tract will be a new feature on geological maps of Ireland.

6. *On Bastite-Serpentine and Troktolite in Aberdeenshire; with a Note on the Rock of the Black Dog. By* Professor T. G. BONNEY, *D.Sc., LL.D., F.R.S., Pres. G. S.*[1]

Bastite-serpentine (as noticed some time since by Professor Heddle) occurs near Belhelvie and on the shore near the Black Dog. The author describes the microscopic structure of this, showing that it consists of olivine and its alteration products, enstatite in various stages of alteration, and a mineral of the spinellid group. Associated with this in the Belhelvie district is a fairly normal troktolite, consisting of a plagioclastic felspar allied to anorthite, olivine, more or less altered, and a little diallage. It closely resembles the typical Volpersdorf rock, but has rather less magnesia and more alumina, corresponding chemically more nearly with a rock described by the author from Coverack Cove, Cornwall. He is of opinion that the two rocks differ somewhat in age, though probably the earlier was still at a high temperature when the later was intruded, and he inclines to the view that the serpentine is the older rock of the two.

The Black Dog has been incorrectly described as consisting of 'crystals of *talc* matted in such confusion as to form both a tough and hard rock.' The rock really consists of quartz, sillimanite, two kinds of mica, an iron oxide (hematite?), and most probably some dichroite, with perhaps a little kyanite. In short, the rock presents a very close resemblance under the microscope to some specimens of the well-known 'cordierite gneiss' of Bodenmais.

7. *On certain Diatomaceous Deposits (Diatomite) from the Peat of Aberdeenshire.* *By* W. Ivison Macadam, *F.C.S., F.I.C.*

The material was found below the peat in certain districts of Aberdeenshire, but principally in the basin in which lie Loch Kinnord and Davin. After removal of the surface peat fuel the lower and more highly mineral portion was cut in blocks and air dried. The substance then consisted of almost pure diatomacea bound together by the remains of sphagnum, equisetacea, &c. Besides being found underlying peat, the substance was also obtained on the shores of Loch Kinnord, and the more pure diatoms were thickly distributed over the bottom of the deeper portions of the lake. These latter, however, from the want of the binding obtained from the marsh plants above stated, could not be rendered readily available for market. An interesting point regarding these deposits was, that, whilst in Loch Kinnord an abundant supply of the diatoms could be obtained, in the neighbouring Loch Davin scarcely a single diatom (recent or fossil) was found. This was probably due to the fact that, whilst the feeding waters of Loch Kinnord flowed from hills consisting of a coarse and much disintegrated granite, and consequently containing a considerable proportion of soluble silica, the Loch Davin waters were obtained from hornblendic mountains, and held much less soluble silica in solution.

The material was principally used for the manufacture of dynamite, and a considerable quantity had been forwarded to the works for this purpose. Other uses could be found for the material, such as the manufacture of ultramarine, for which from the very small proportion of iron present the diatomite was more especially to be recommended. As an absorbent, it was of fully double the value of the ordinary German varieties of Kieselgpohr.

The paper was illustrated by specimens and diagrams.[1]

8. *List of Works on the Geology, Mineralogy, and Palæontology of Staffordshire, Worcestershire, and Warwickshire.* *By* W. Whitaker, *B.A., F.G.S., Assoc.Inst.C.E.*—See Reports, p. 780.

FRIDAY, SEPTEMBER 11.

The following Papers and Reports were read :—

1. *The Volcanoes of Auvergne.* *By* Tempest Anderson, *M.D., B.Sc.*

The modern dry plate process of photography has placed in the hands of geologists the power of rapidly and faithfully recording and reproducing before an audience of any size many geological and especially volcanic phenomena which it would be impossible adequately to describe in words.

By means of the oxyhydrogen lantern a number of photographs were shown on the screen which had been taken by the author in the volcanic district of the Auvergne and adjacent parts of the Velay and Vivarais, in Central France.

Cones of scoriæ with craters were contrasted with the Domitic Puys in Auvergne, and these again with the Phonolitic hills in the district of the Mezenc. The appearances of various lava streams both on the surface and where exposed in sections were shown, especially those of the valleys of Jaujac and Montpezat. Lakes in extinct craters were contrasted with those formed in pre-existing valleys behind dams of volcanic ejecta, and the general scenery of volcanic rocks was compared with that of other adjacent formations.

2. *On the Re-discovery of lost Numidian Marbles in Algeria and Tunis. By* Lieut.-Colonel R. L. Playfair.

The author explained that the name itself was a misnomer, as they are not found within the limits of Numidia proper, but in the province of Africa and in Mauritania. Most of the 'Giallo antico' used in Rome was obtained from *Simittu Colonia*, the modern Chemtou, in the valley of the Medjerda, the quarries of which are now being extensively worked by a Belgian company; but the most remarkable and valuable marbles are found near Kleber, in the province of Oran, in Algeria. There, on the top of the Montagne Grise, exists an elevated plateau, 1,500 acres in extent, forming an uninterrupted mass of the most splendid marbles and breccias which the world contains. Their variety is as extraordinary as their beauty. There is creamy white, like ivory; rose colour, like coral; Giallo antico; some are as variegated as a peacock's plumage; and on the west side of the mountain, where there has been a great earth-movement, the rock has been broken up and re-cemented together, forming a variety of breccias of the most extraordinary richness and beauty.

Colonel Playfair exhibited specimens of the principal varieties, to prove that his descriptions were not exaggerated. The beauty of these marbles has been recognised by the trustees of the British Museum, who are now mounting the sculptures of the Parthenon and the Mausoleum on basements of them. Specimens may also be seen in the Mineralogical Room of the British Museum, at South Kensington.

The marble mountain belongs to Signor del Monte, of Oran, and, although it is not being worked as it ought to be, blocks can be obtained at a cost of about 18*l.* per cubic mètre, ready for shipment.

3. *Second Report on the Rate of Erosion of the Sea Coasts of England and Wales.*—See Reports, p. 404.

---

4. *The Chasm called the Black Rock of Kiltearn. By* William Watson.

This is a narrow ravine in conglomerate: its length is about $1\frac{1}{4}$ mile; its depth varies from 100 to 130 feet; its breadth at the top varies from 12 or 15 to about 30 feet. The river which flows through the ravine is the Altl-Gránda; it drains Glen Glass (above the ravine); the water flows into Cromarty Firth.

The author refers to popular views held to explain the formation of the ravine —earthquakes and fracture, and shows that these are inadequate. The ravine has clearly been produced by erosion, of which the marks are still visible on the sides; the difficulty is to explain how erosion could have produced a gorge of this kind without weathering action and floods having denuded the sides.

Above the gorge in Glen Glass was once a lake. This had been silted up to the height of about 80 feet with sand, washed out of the Glacial *débris* of the glen. When the barrier that confined the lake gave way the river flowed over the surface of the conglomerate, carrying with it much sand from the lake-silt, and using this as a means of rapidly eroding the rock. When the chasm was deep enough to prevent the floods from overflowing the banks the sides could not be widened to any great extent. The disproportion between the deepening and widening process has been maintained, thus causing the steep-sided narrow glen. The excavation now going on is small, whilst the weather has some effect on the sides; so that ultimately an ordinary valley will be produced.

---

5. *The Bass of Inverurie, a fragment of an ancient Alluvial Bed. By the* Rev. John Davidson, *D.D.*

The Bass of Inverurie, a green conical hill about 50 feet high and singularly symmetrical, stands isolated in a corner of the united river valleys of the Don and Ury, which latter stream washes its base.

Its form and position were until lately accepted as proving it to be of artificial origin, and speculation dealt only with hypotheses of the reason of its being erected. Some of these, being of a superstitious character, increased the unwillingness to have the mound dug into which veneration for its antiquity and its traditional history occasioned. The character of the great mound was discovered by accident in 1883, when a burying ground was being prepared around its base.

The Bass has a prolongation half the height called the Little Bass. In laying out the graveyard a walk was made round the conical portion, so as to complete the outline of the cone. A way had to be excavated between the Bass and Little Bass. The work showed for a day or two a vertical section, which, being observed, was examined by a geological expert and pronounced to be clear evidence that the hill was produced by successive deposits of sand laid down in the valleys of the Don and Ury, until a sand bed lay there whose surface was of the height of the top of the Bass. Upon that level, 40 feet higher than the present level of the Don and Ury, these streams flowed before the Bass began to be formed; and in course of time it was gradually formed by denudation, something accidentally protecting a spot of surface while the streams washed away the soil around. The river beds were gradually deepened, while the Bass, once begun to stand up out of the flood, got broader and broader, turning the two converging streams aside.

The alluvial origin of the Bass infers the existence of a breadth of flowing water over the whole range covered by the sand bed, which can be traced five miles back from the Bass in the line of both rivers. The existence of that lake infers the existence of others between it and the sea. Ordnance levels and existing rocky narrows in the line of the Don point out the outlines of those lakes.

The continuing preservation of the form of the Bass, notwithstanding that the Ury impinges upon it at right angles, is due to the circumstances that a bed of boulder clay 30 feet wide underlies the Ury and the centre of the Bass. The boulder clay was discovered in building a wall for the graveyard, and the bed has since been found a mile south in digging a well at the Inverurie paper mills. It is there 46 feet thick.

---

7. *The Direction of Glaciation as ascertained by the Form of the Striæ. By* Professor H. Carvill Lewis.

As there seemed to be a disagreement between certain Scotch geologists and the Irish geologists regarding the inferences as to the direction of glaciation to be deduced from the form of glacial striæ, the author was led to bring forward some observations of his own, made in America and in Great Britain, which threw light upon the disputed point.

Well-preserved striæ are frequently blunt at one end and tapering at the other, the shorter ones sometimes resembling the characters used in the cuneiform inscriptions. This form may be seen in striæ of all sizes—from those several yards in length, when the blunt end may be an inch or more in breadth, to the finest scratches, where a microscope is necessary to detect any difference between the two ends.

As shown in the Reports of the Boulder Committee of the Royal Society of Edinburgh[1] and elsewhere, certain Scotch geologists regard the blunt end as the point of impact of the striating agent, and as therefore pointing to the direction from which the motion came. On the other hand, the Irish geologists[2] interpret the shape of the striæ as indicating motion in the opposite direction, believing the tapering end to point to the direction from which glaciation proceeded. The point

[1] Fifth Report, pp. 18–20, 29, 58; and Seventh Report, p. 18.

[2] *Memoirs Geolog. Surv. of Ireland.* Explanation to sheets 86, 87, 88, p. 55 Explanation to sheet 193, p. 18, &c.

at issue is of importance, especially in outlying islands and elsewhere, where other indications of the direction of glaciation fail.

In Pennsylvania, which is crossed from east to west by the terminal moraine of the great ice-sheet, and where the glaciation is uniformly in a southward direction, the author had observed that the blunt ends of the striæ, where flat surfaces were studied, were always to the south.[1] In certain instances the mode of formation of the striæ was also indicated by their shapes, which showed that a stone pushed along under the glacier had ground in deeper and deeper until, in some cases, it stopped or hopped out, in other cases was ground down to another cutting edge, and in others *turned over* and began its work of engraving by a fresh and sharp corner. The peculiar gouges at the farther end of certain striæ showed a sort of slow rocking motion in some stones before they finally turned over.

The author's observations in Ireland, both at localities where there could be no doubt as to the direction of glacial movement, and at localities where such direction was not previously known, led to conclusions entirely in harmony with those already reached in Pennsylvania and with those held by the Irish geologists.

One of the best examples falling under the former category was among the local glaciers in the mountains of the Dingle promontory, a region not invaded by the great confluent ice-sheet of Central Ireland. The striated beds of these small glaciers, beginning in a 'corry' and bounded below by a semicircular terminal moraine, are beautifully defined and afford good opportunities for striæ study. It was found that *the wedge-shaped striæ are blunt at the advancing end except on convex downward surfaces, where the reverse is the case.* While this rule does not hold good for every individual scratch at a given locality, it has been found most useful when applied to striated surfaces in general.

At Glengariff, where some finely striated surfaces occur, a number of tracings were taken directly from the rock, which clearly show the broader ends of most of the striæ to be to the south, the direction toward which the glacial stream advanced. Similar observations were made at several localities south of the Shannon.

Finally, as an instance where the direction of glaciation was previously unknown, certain striæ were described which the author had observed on the top of the cliffs facing the Atlantic at Kilkee. These point N. 58° W. and S. 58° E., and the question to be determined was whether the glaciation proceeded from the Atlantic towards the land, or whether it went north-westward and out to sea. The form of the striæ alone decided it. Their broad blunt ends were, as a rule, toward the N.W.—the surface being horizontal—a fact which, taken in connection with other observations made about the mouth of the Shannon, showed that a great ice stream had flowed westward along the valley of the Shannon, and had opened out fan-shaped as it plunged into the sea.

---

8. *Proposed Conditions to account for a former Glacial Period in Great Britain, existing under similar meteorological conditions to those that rule at the present time. By* W. F. Stanley, *F.G.S., F.R.M.S.*

This paper may be considered as a continuation of a paper read by the author last year, in which it was argued that climates did not appear to be greatly influenced by excentricity of the earth's orbit or the position of winter perihelion, as assumed by Dr. Croll and other physicists of the present time. The southern hemisphere, assumed to be the colder, was shown by observation to be the warmer. Therefore, looking to other causes for former glaciation, the author suggested that these were possibly local phenomena which were dependent upon geographical conditions. The former glaciation in Great Britain and Western Europe was supposed by the author to be due to the following conditions:—

1. The non-existence of the Isthmus of Panama, by which the warm southern tropical current, now deflected by Cape St. Roque, in South America, into the

[1] On the Terminal Moraine in Pennsylvania and Western New York. Report Z. *Second Geolog. Survey of Penn.*, pp. 33, 85, 86, 107, 275.

Northern Atlantic, formerly flowed into the Pacific Ocean, leaving the entire Northern Atlantic at its mean normal latitude temperature in comparison with other oceans.

2. A former depression of North America in W. long. 80° to 90°, by which the northern tropical current, now deflected by resistance of land through the Straits of Florida, formerly flowed where we have at present the Mississippi valley, the great American lakes, and Hudson's Bay, by which cause warm currents bathed the western coast of Greenland, and, turning to the north of this continent, produced a compensating return current from the Arctic regions which flowed southward along Western Europe and Great Britain, bringing with it icebergs, as at present the compensating current to the Gulf Stream brings icebergs to the coast of Labrador.

3. Higher elevation of some interior part of Great Britain of the older strata now denuded, by which, at the temperature then ruling, glaciers flowed from the interior.

For the general principles of oceanic circulation reference was made to the discussion of this subject, given by the author in his work on fluids.

---

9. *On the Fynnon Beuno and Cae Gwyn Bone-Caves, North Wales.* *By* H. Hicks, *M.D., F.R.S., F.G.S.*

In the 'Proceedings of the Geolog. Assoc.' vol. ix. No. 1, I have given an account of the discovery of two bone-caves in the carboniferous rocks on the east side of the Vale of Clwyd, North Wales, and of the researches carried on in those caverns by Mr. Luxmoore, of St. Asaph, and myself, in the summers of 1883 and 1884. This summer, by the aid of a grant from the Royal Society (the Government grant), we were enabled to employ a staff of workmen, under our personal supervision, to explore these caverns more thoroughly, and with very satisfactory results. Our main object was to gain a clear idea of the physical conditions of the area when the caverns were filled with the deposits, and of the manner in which the remains had been conveyed into them. These points we think we have been able to prove to satisfaction, but it may be advisable to continue the researches for the purpose of obtaining as much confirmatory evidence as possible.

In the *Cae Gwyn Cavern* all the deposits were entirely undisturbed except by burrowing animals when we first discovered it, and great care was taken throughout to notice the conditions of the materials. The deposits in this cavern consisted of, first, a reddish clayey earth, varying in depth from two to four feet. Below this was found a more compact deposit consisting of thin layers of a fine marly clay, about 18 inches in thickness, and under this the material containing the bones This material consisted of a reddish clay, with sand in places, and contained many boulders similar to those found in the boulder clays of the district. Large fragments of a stalagmite floor and of stalactites occurred also in it, showing that the water action which disturbed the original materials in the cave must have been of a violent nature. Under this was found a gravelly deposit, containing fragments mainly from the hills above, and no bones. In this cavern the deposits, except the lowest, have been cleared out to a distance from the entrance of over 150 feet. This cavern is for the most part a true tunnel cavern with well smoothed roof and sides. The largest chamber has just been reached at a little over 150 feet from the entrance. It is over 11 feet in length and 9 feet in height. The other chambers are small, being mainly dilatations of the tunnel, which varies from 3 to 9 feet in width. Extending from a small chamber, about 45 feet from the entrance, there is another branch tunnel whichhas been explored to a distance of about 16 feet.

The bones discovered in this cavern, according to Mr. W. Davies, F.G.S., of the British Museum, to whom they have been submitted, belong to the lion, hyæna, bear, badger, wolf, fox, great Irish deer, reindeer, red deer, roebuck, rhinoceros, and horse. A flint scraper was also found last year in association with the remains at a distance of 45 feet from the entrance.

The *Fynnon Beuno Cavern* is partly a fissure and partly a tunnel cavern. From

the entrance inwards for a distance of about 40 feet it is a true tunnel cavern, and there is a branch tunnel extending from this for a further distance of over 50 feet, ultimately opening out on the hill side above the main entrance. Another tunnel communicates with an extensive fissure cavern, which had evidently been disturbed at some time by mining operations, though I could obtain no information as to when. In the undisturbed parts of this cavern the deposits were of a similar character to those in the Cae Gwyn Cave. This cavern, however, being for some extent an open cavern, had probably been inhabited in Neolithic, or perhaps later times, as a quantity of charcoal was found at two points at distances of from 20 to 24 feet from the entrance. Several well-worked flint flakes were found at different points in this cavern, in association with bones of the mammoth, rhinoceros, &c. Dr. Evans recognised them as of the type of the wrought flakes found in Kent's Cavern. They also, like those found in Kent's Cavern, are white and porcellanous, and all show indications of having been used, but not rolled by water action. Worked bones and others broken by man were also found. The bones, which were exceedingly plentiful in the cavern, were found to have been gnawed freely, and evidently when in a fresh condition, hence showing clearly that they had been conveyed into the cavern soon after the animals had died. Some *album græcum* was also found in each of the caverns, therefore the evidence points clearly to their having been dens occupied by the beasts of prey. I think we are quite justified also in supposing, from the positions of the flakes and worked bones, that the caverns were occupied by man, or at least that the district was inhabited by man when the mammoth, rhinoceros, reindeer, hyæna, &c., roamed about the area.

The bones found in this cavern belonged to the following animals, viz., lion, wild cat, hyæna, bear, wolf, fox, wild boar, great Irish deer, reindeer, red deer, roebuck, bos, mammoth, rhinoceros, and horse. The remains were much more plentiful in the Fynnon Beuno than in the Cae Gwyn Cave. Among the specimens found in the two, there were over 80 jaws belonging to various animals, and more than 1,300 loose teeth, including about 400 rhinoceros, 15 mammoth, 180 hyæna, and 500 horse teeth. Other bones and fragments of bones occurred also in very great abundance.

As these caverns are about 400 feet above present sea level, and nearly 300 feet above the river Clwyd (the height given in my paper to the Geologists' Association was understated), it is clear that great physical changes must have taken place in this area since the time that the marine sand was conveyed into these caverns. The broken stalagmite floor, sometimes 10 to 12 inches in thickness, and the broken stalactites 6 to 8 inches across, show that the water action must have been also of a violent nature. The position of the bones in some places under still adherent parts of this stalagmite, and the presence of marine sand in the hollow parts of the bones, show that the bones must have been in the caverns before the sea finally receded from them. The presence also of a material, in every respect like the boulder clay of the district filling up the caverns, points to the probability that the so-called Upper Boulder clays of this district were deposited for the most part at the time, or subsequent to the infilling of these caverns. Along the hill-sides in the ravine in which the caverns are situated, sands and clays similar to those found in the caverns, and containing marine shells, are found at about the same horizon and in the hills to the S.E. at much greater elevations. Cae Gwyn Cave is over 60 feet, and Fynnon Beuno 42 feet above the level of the little stream, a tributary of the Clwyd in the ravine in which they are situated. These facts suggest the following as the probable changes indicated by the deposits in the caverns:—The lowest deposit in the caverns, consisting almost entirely of local materials, was introduced into them by the river which then flowed in the valley at a very much higher level than at present. As time went on the valley deepened, and the caverns were above the reach of the floods. They then became the abode of hyænas and other beasts of prey. Subsequently there was a period of great submergence, and when the caverns were on a level with the sea, they were filled with sandy materials and the bones were embedded in it. The following are the results which have to be accounted for: (*a*) The infilling of the caverns by local gravels; (*b*) the occupation of the caverns by beasts of prey; (*c*) the formation

of the stalagmite; (*d*) the breaking up of the stalagmite floor and the introduction of the boulder clay. The position of the caverns almost at the crest of a ridge of carboniferous rocks makes it clear that the boulder clay could not have been introduced by streams, therefore the only conclusion I can arrive at is that during a period of great submergence, either during or subsequent to the glacial epoch, the material was introduced by marine action.

---

10. *Note on Specimens of Fish from the Lower Old Red Sandstone of Forfarshire. By the* Rev. Hugh Mitchell.

The author stated that at the meeting of the Association in 1859 he exhibited specimens of fish which were afterwards described by Sir P. Egerton in the Tenth Decade of the Geological Survey. With these specimens was a beautiful spine, the relations of which were unknown, but of which other portions have since been found. The author submitted descriptions which he regarded as sufficient to justify the founding of three new species. The specimens were from Farnell and Turin.

SATURDAY, SEPTEMBER 12.

The following Papers and Report were read:—

1. *The Elgin Sandstones. By* J. Gordon Phillips.

The question of the age of the reptiliferous sandstones of Elgin is not yet settled. Murchison and Sedgwick decided on stratigraphical grounds that they belong to the Old Red formation, which was afterwards confirmed by Palæontology. Later discoveries, however, of reptilian remains (*Stagonolepis, Telerpeton,* and *Hyperodapedon*), raised the question of the age, one party maintaining that the reptiles were of Triassic origin, and the other, of the upper beds of the Old Red. The opinions of the supporters of the Triassic theory were gradually accepted, owing to palæontological discoveries, and, indeed, so sure were palæontologists they were right, that one said if the sandstones turned out to be Old Red, he would give up geology altogether, and another said he would not believe they were Old Red until he saw a reptile with a *Holoptychius* in its mouth. There were a few geologists who still clung to the old belief, among them being Dr. Gordon of Birnie and the late Professor Nicol. The question, however, has again been opened by the discovery of reptilian remains and of Holoptychian remains in the same quarry, the latter underlying the former, but there is a bed of conglomerate, five feet thick or thereabouts, between the two deposits. This bed has died out in the meantime, and it is doubtful if it will reappear; the Old Red may be found passing under the reptiliferous in natural order right on the coast.[1] Indeed there is evidence of the existence of *Holoptychius* a little west of Stotfield, in ground which has hitherto been deemed purely reptilian, which tends to confirm that idea. This quarry is situated on the ridge which runs south-west by west to north-east by east in the immediate vicinity of Elgin, and called Cutties Hillock. In Professor Judd's admirable paper on the 'Secondary Rocks of Scotland,' published in 1873, he has the two systems faulted against each other above Findrassie, but the fact of reptiles and a *Holoptychius nobilissimus* having been found in this quarry in deposits apparently conformable shows there is no such powerful fault. But when Professor Judd's paper was written no other conclusion could be arrived at. He knew that reptilian remains had been got immediately to the north of the

[1] Since the above was written the workmen have, on the north side of the quarry, gone down into sandstone, which I regard as being identical with that containing *Holoptychius*, and, in my opinion, the two deposits are lying apparently perfectly conformable, with no conglomerate between. It seems to me to have died out altogether, only an occasional pebble appearing.

ridge at Findrassie, and he also knew that at least one Old Red fish had been got at its southern base at Laverock Loch, so that it was the most probable explanation to indicate the presence of a fault. And indeed, at the east end of the ridge near Bishopmill, there is evidence of disturbance, though it in no way affects the quarry at Cutties Hillock. After the quarry (Cutties Hillock) was opened, the lessees, for the purpose of finding out the building qualities of the stone, sank a pit through the bed of conglomerate, mentioned above, a distance of about 22 feet, and in this pit was found a *Holoptychius*. The pit was subsequently filled up, as the stone was not found suitable for building purposes. This necessitated the cutting of a trench again into the Holoptychian sandstone, to see if the overlying beds are conformable or unconformable, which is now being proceeded with.[1] In the quarry there is also a sand dyke dividing it, but reptilian remains have been found on both sides. What these reptiles are has not yet been determined, though Huxley is understood to have said that he believed one of them to be *Dinosaurian*. All these reptilian remains, with the exception of one, were found about the same level in the quarry, indeed so much is this the case that the workmen call it 'the fossil joint.' The texture of the Holoptychian sandstones and the reptiliferous sandstones is different. The former is fine, and the laminæ are well marked, while in the other it is more rough and angular, but they appear to have been both drawn from the same sources of granite waste. We have not made microscopic sections, but have examined the sand of which the two deposits are formed, and there is little apparent difference. They are composed of quartz, felspar, and mica, the reptiliferous being, if anything, a little more felspathic in character. Such a case, so far as we know, is unique. Reptile-bearing beds have never before been found lying on the Old Red and apparently conformable. The question is, are the reptiliferous beds Triassic or Upper Old Red? Looking at the matter from an Old Red point of view, it is difficult to understand why reptiles could not have existed in the Upper Old Red if the conditions of life were favourable, and we feel no assurance that the conditions of life should not have been favourable when the Elgin sandstones were deposited. If they are Triassic, what has become of the vast periods which lie between the two systems, and why should these reptiles be confined to a few miles of north-eastern Scotland in the vicinity of Elgin? The palæontologist would answer that some of these reptiles have been found in the Trias in other parts of the world (England, Africa, and India), and that Old Red fishes and reptiles had never been found associated together in the same beds. All that we ask is that the question may be kept open for a time, so that all possible evidence may be obtained. We acknowledge the full weight of palæontological evidence, and all that geologists owe to that great science, but it is possible that in some cases it may be stretched too far. All that we wish to ascertain is the truth, and with present light we cannot say that it has been reached. We want more proof.

---

2. *Preliminary Note on a new Fossil Reptile recently discovered at New Spynie, near Elgin.* *By* Dr. R. H. Traquair, *F.R.S.*

Of this most important fossil the author had as yet only seen a photograph, submitted to him by Professor Judd, F.R.S., the President of the Section. This photograph represents pretty nearly a vertical longitudinal section of a reptilian skull, of which one very prominent feature is the presence in the upper jaw of a large conical tusk projecting downwards and forwards, immediately behind the premaxillary part of the cranium. This tusk is seen only in impression, but the cast of the internal cavity, which is well shown, indicates that it grew from a permanent pulp. No evidence of any other teeth is visible, and the whole appearance of the skull as seen in the photograph, with the position and shape of the tusk, indicate that the reptile here represented, if not actually belonging to the genus *Dicynodon*,

[1] This trench, when finished, was examined by Professor Bonney, Professor Judd, and myself. There was the appearance of a very slight unconformity in my opinion, but such appearances frequently occur in the Elgin Sandstones caused by false bedding.

is certainly a member of the group of *Dicynodontia.* Geologists will not underrate the value of this discovery in its bearing on the question of the age of the reptiliferous sandstone of Elgin.

---

3. *Report on the Fossil Plants of the Tertiary and Secondary Beds of the United Kingdom.*—See Reports, p. 396.

MONDAY, SEPTEMBER 14.

The following Papers were read :—

1. *The Highland Controversy in British Geology : its Causes, Course, and Consequences. By* Professor CHARLES LAPWORTH, *LL.D., F.G.S.*

PART I.

The author gave a *résumé* of the views of the earlier geologists respecting the geological age and possible mode of formation of the Highland Metamorphic rocks, and sketched in brief the rise and progress of the controversy between Sir R. Murchison and his followers on the one hand, and Professor Nicol of Aberdeen on the other, till its temporary close in 1855 by the publication of the Highland Memoir of Murchison and Geikie. He then reviewed the re-opening of the controversy by Dr. Hicks in 1877, and the work of the Archæan geologists, up to the date of publication of Dr. C. Callaway's paper in 1883, in which Nicol's view of the great physical break between the Palæozoic rocks and the Eastern or Upper Gneissic series was shown to be correct; but the so-called Eastern Gneiss was provisionally erected into a new Archæan system, having the Arnaboll Gneiss as its lower member.

The author next gave a summary of his own views, as deduced from his personal study of the Durness-Eriboll district in 1882 and 1883, illustrating them by coloured maps and sections. He held that (exception being made of the local Torridon sandstone) the only rock-formations in the Durness-Eriboll area are, as Nicol originally contended,—(1) the Archæan or Hebridean gneiss,and (2) the Palæozoic quartzites, fucoid beds, and limestones.

There is no conformable ascending succession from the Palæozoic rocks into the Eastern Metamorphic series. The line of contact is, generally speaking, a plane of dislocation, and where this is wanting the Palæozoic rocks rest unconformably upon one of the members of the Eastern Gneiss. The present physical relations of the Eastern Metamorphic series are the effect of lateral crust-creep, by which the Eastern Metamorphic rocks have been forced over the Palæozoic rocks to the west, often for many miles. This Eastern Metamorphic series is composed of two petrological members, the *Arnaboll gneiss* to the west, and the *Sutherland schists* and gneiss to the east, having between them a series of *variegated schists* possessing characters common to both. The Arnaboll gneiss is simply the easterly extension of the Hebridean of the west. The remaining gneisses and schists of the Eastern Metamorphic series are mainly composed of remetamorphosed Hebridean, with included patches of igneous and Palæozoic material. The planes of schistosity which divide the layers of the Upper Gneissic series are not planes of bedding, but planes of dislocation. The present dip, strike, and mineralogical characteristics of these rocks have been given to them since Silurian times, by the agency of the great earth movements. In some instances the original structures of the rocks are still recognisable ; frequently, however, they are more or less obliterated, the old minerals have disappeared as such, and new minerals have been developed. The Eastern Gneissic series of this area has thus no pretension whatever to the title of a sedimentary rock-system. It is a petrological rock-massif, a metamorphic compound, composed of local elements of different geological ages. In all their essentials

these views appear to agree with those worked out independently by Messrs. Peach and Horne in 1884.

PART II.

In the second part of his paper the author gave a summary of the work accomplished among the metamorphic rocks of the Alps and Eastern Germany by Heim and Lehmann, and described the several types of rock metamorphism found in the Eriboll district, as worked out by himself.

The Arnaboll (Hebridean gneiss), can be traced stage by stage from spots where it retains its original strike and petrological characters, to others where it acquires the normal strike and mineralogical features of the ordinary Sutherland schists. The old planes of schistosity become obliterated and new ones are formed; the original crystals are crushed and spread out, and new secondary minerals (mica and quartz) are developed. The most intense *mechanical* metamorphism occurs along the grand dislocation (thrust) planes. The gneisses and pegmatites resting on that plane are crushed, dragged, and ground out into a finely laminated schist (*mylonite*; Gr. *mylon*, a mill), composed of shattered fragments of the original crystals of the rock, set in a polarising cement of secondary quartz, the lamination being defined by minute inosculating lines (fluxion lines) of kaolin or chloritic material, with secondary crystals of a micaceous mineral. Whatever rock rests immediately upon the thrust-plane, whether Archæan, Igneous, or Palæozoic, &c., is similarly treated, the resulting mylonite varying in colour and composition according to the material from which it is formed.

The variegated schists, which form the transitional zones between the Arnaboll gneiss and Sutherland mica-schists, are all essentially mylonites in origin and structure, and appear to have been formed along great dislocation planes, some of which still show between them patches of recognisable Archæan and Palæozoic rocks. These variegated schists (phyllites or mylonites), differ locally in composition according to the material from which they have been derived, and in petrological character according to the special physical accidents to which they have been subjected since their date of origin, forming frilled schists, veined schists, glazed schists, &c. &c.

The more highly crystalline flaggy mica-schists &c. which lie immediately to the east of the zones of the variegated schists, appear to have been made out of similar materials to those of the variegated schists, but to have been formed under somewhat different conditions. They show the fluxion-structure of the mylonites, but while the differential motion of the component particles seems to have been much less, the chemical change was much greater. In some of these crystalline schists (the augen-schists), the larger crystals of the original rock from which the schist was formed are still individually recognisable, while the matrix now containing them is a secondary crystalline matrix of quartz and mica arranged in the fluxion-planes. While the *mylonites* may be described as microscopic pressure-breccias with fluxion-structure, in which the interstitial siliceous and kaolinitic paste has only crystallised in part; the *augen-schists* may be described as pressure-breccias with fluxion-structure, in which the whole of the interstitial paste has crystallised out. The *mylonites* were formed along the thrust-planes, where the two superposed rock-systems moved over each other as solid masses, the *augen-schists* were probably formed in the more central parts of the moving system, where the all-surrounding pressure forced the rock to yield somewhat like a plastic body. Between these augen-schists there appears to be every gradation, on the one hand to the mylonites, and on the other to the typical mica-schists composed of quartz and mica.

Like the mylonites, the crystalline augenites and micalites present us with local differences in chemical composition (calcareous, hornblendic, quartzose, &c.) They also show corresponding structural varieties due to secondary changes (frilled, veined, glazed, &c.), as well as others due to the presence of special minerals (garnet, actinolite, &c. &c.).

2. *The Geology of Durness and Eriboll, with special reference to the Highland Controversy. By* B. N. Peach, *F.R.S.E., and* J. Horne, *F.R.S.E.*

With the permission of the Director General of the Geological Survey, the authors gave an outline of the geological structure of the Durness-Eriboll region, illustrated by a series of horizontal sections. They showed that the Silurian strata of Durness are arranged in the form of a basin bounded on the east side by powerful faults disconnecting them from the same series in Eriboll. The order of succession in the two areas is identical from the basal quartzites to the horizon of the Eilean Dubh limestone group. On the west side of Loch Eriboll the basal quartzites rest unconformably on the Archæan gneiss, but on the eastern shore there is conclusive evidence of the repetition of various members of the Silurian series by a remarkable system of reversed faults culminating in a great dislocation which has thrust the Archæan gneiss over the truncated edges of the quartzites, fucoid beds, serpulite grits, and basal limestone. Reference was made to the effect of these mechanical movements on the Silurian rocks and to the development of new planes of schistosity in the gneiss above the thrust plane. At intervals, small patches of the basal quartzites are met with throughout this mass of Archæan gneiss, which are abruptly truncated by great reversed faults, but in the district between Eriboll and Assynt the whole Silurian succession from the basal breccia to the lowest limestone occurs repeatedly above the first great thrust plane, separated by wedges of highly sheared gneiss. It was shown that the alteration produced by each successive displacement gradually becomes more pronounced as the observer passed eastwards across the area. The old north-west strike of the Archæan gneiss gave place to a new foliation running more or less parallel with the strike of the thrust planes; the felspathic basal quartzites and the 'pipe-rock' pass into quartz schists and mica schists, and the Silurian limestone is felted with the crushed Archæan gneiss. Reference was next made to the outcrop of the great thrust plane extending from the Whitten Head Coast far to the south, which ushers in a highly schistose series with a N.N.E. and S.S.W. strike. After describing the lithological characters and order of succession of the eastern schists, the authors stated that the new planes of foliation had been superinduced by the mechanical movements that took place between Lower Silurian and Old Red Sandstone time, and that along these new planes a rearrangement and recrystallisation of mineral constituents took place, resulting in the production of crystalline schists. Applying the knowledge thus obtained from the study of the eastern schists to the undisturbed Archæan masses, they had found conclusive evidence of similar mechanical movements in Pre-Cambrian time. Each plane of schistosity exhibits the parallel lineation like slickensides trending in the same direction over a vast area, while the minerals were oriented along these lines. From a consideration of these phenomena the authors inferred that regional metamorphism need not necessarily be confined to any particular geological period, and further that the planes of foliation or schistosity in those areas which had been subjected to regional metamorphism were evidently due to enormous mechanical movements which had induced molecular changes in crystalline and clastic rocks.

---

3. *Preliminary Note on some Traverses of the Crystalline District of the Central Alps. By* Professor T. G. Bonney, *D.Sc., LL.D., F.R.S., Pres.G.S.*

During the past four years I have made several traverses of the Central Alps from north to south, and venture to lay before the Section the general results as bearing in some respect on the geology of the Highlands.

1. The ordinary rules of stratigraphy as learnt from most lowland districts are commonly quite inapplicable to the Alps. The most highly crystalline and the older beds often form the higher parts of a mountain region, the newer the lower. The newer beds frequently appear to underlie and dip regularly beneath the older. Gigantic folds, overturns, and overthrust faults abound. The true stratigraphy of

a district can only be worked out by the exercise of patient and cautious induction from observations extended over a wide area.

2. The non-crystalline rocks of the Alps are of various ages. There are some of Carboniferous age, but the great period of continuous deposition generally begins with some part of the Trias. The conglomerates, which often occur at the base of the non-crystalline deposits, indicate that the principal metamorphism of the crystalline series was anterior to both these epochs. There is at present no reason to suppose that either in the Central Alps or for some distance on each side there are any representatives of the earlier Palæozoics. I believe that the conglomerates at the base of the Carboniferous contain fragments of the later crystalline rocks of the Alps as well as of some of the earlier—though I do not assert that these crystalline rocks have undergone no modifications since Carboniferous times.

3. In the heart of the principal Alpine chains, and apparently at the base of everything, are coarsely crystalline gneisses. These differ little from granites, except that they generally—almost always—exhibit a certain foliation, and occasionally seem to be interbedded with thin seams of micaceous schists or flaggy fine-grained beds.

4. On examining these latter we find reason to believe that they are generally due to crushing. Their strike agrees with that of the apparent foliation in these older rocks, and with that of a foliation which is also present in the newer crystalline rocks. This corresponds with the strike of the main physical features of the district, and with the cleavage in the included troughs of sedimentary rock. It runs for great distances with remarkable uniformity, *e.g.*, from the Maderanerthal to the upper part of the Lukmanier Pass the strike of this foliation does not materially vary from W.S.W.-E.N.E.

5. This apparent foliation is due to the development of extremely thin films of a micaceous mineral. In many cases it causes the rock to bear the aspect of a highly micaceous schist; yet, on examining a transverse section, it is seen distinctly to be a crushed gneiss; *i.e.*, though so conspicuous, it is a mere varnish. As it thus differs materially from a true foliation, it would be convenient to give it a name, and I should propose to call it the 'sheen surface.' It is, in fact, a kind of 'cleavage foliation,' that is, a foliation due to cleavage, and subsequent to it. But though from certain points of view so conspicuous, its minerals often constitute a very small part of the mass of the rock.

6. The pressure which has produced this 'sheen surface' has in many cases affected the orientation of the minerals, which are present in the true 'foliation' layers of the more distinctly foliated, *i.e.*, mineral-banded, rocks. It has affected these minerals as pressure affects the constituents of a sedimentary rock.

7. In the crystalline schists very commonly the 'sheen surface' corresponds with the original foliation surface, as in the slates the cleavage sometimes does with the bedding. This is due to the fact that the axes of the great folds often make a very high angle with the horizon. It may, however (like a cleavage surface), be seen crossing the foliation at all angles.

8. Thus a non-foliated crystalline rock may be rendered to some extent foliated by pressure (followed by a certain amount of mineralisation); *i.e.*, some gneisses may be formed by crushing from granites, some schists out of other igneous rocks. It may obliterate an earlier foliation, or it may intensify it, or it may produce an independent and more fissile foliation.

In this sense gneiss may be said to pass into granite, because a rock which is now, both macroscopically and microscopically, a gneiss may prove to be a granite which has in some parts yielded to pressure more than in others.

9. As we pass outwards from the great central granitoid masses we come to gneisses and schists where the evidence of some kind of stratification becomes more marked; bands of crystalline limestone, quartzite and granulite being associated with mica schist of many kinds—simple, garnetiferous, staurolitic, actinolitic, and the like—the bands of different mineral character and composition varying from mere streaks to layers which are many yards in thickness. In fact, the above-named rocks are associated exactly as limestones, sandstones, and clays are associated in the ordinary sedimentaries.

10. Although the crushing of a crystalline rock *in situ*, or the squeezing and shearing of a breccia or conglomerate of crystalline fragments, occasionally gives rise to local difficulties, these are on a small scale, and sedimentary beds belonging to the Palæozoic or later periods of deposition are generally readily distinguishable from the whole of the crystalline series. Though folded and faulted in the most extraordinary manner, the members of the two series can generally be separated, and in the Alps there is no evidence of a mingling of the one with the other in the process of rolling out or squeezing together; so that after patient study and microscopic examination we can generally decide without hesitation whether a particular set of rocks has originated from the crystalline or the sedimentary series. I do not say that we can always decide whether a schist or a gneiss has originated from an igneous rock or from an older schist or gneiss, but I think that in the Alps we can say that it has originated from one of these. Fortunately, intrusive rocks are very rare in the Palæozoic and later deposits in this part of the Alps.

11. Thus, although the Tertiary metamorphism of the Alpine rocks is very important, it is more pretentious than real, and its effects seem to have been the greatest where it has found a rock already crystalline to act upon. Hence I believe that every true gneiss and schist in the Alps is much older than the Carboniferous, and is probably older than any member of the Palæozoic period.

---

4. *Some Examples of Pressure-Fluxion in Pennsylvania.* *By* Professor H. Carvill Lewis.

The three localities in Pennsylvania described in this paper lie in an area which had been especially studied by the author for some years back, and had led him to conclusions similar to some of those recently announced as the result of studies in north-western Scotland, which have justly attracted widespread attention.

1. A zone of ancient crystalline rocks extends across south-eastern Pennsylvania, near Philadelphia, which is generally believed to underlie the lowest Cambrian strata and to be of Archæan age. This zone is about a mile wide where it crosses the Schuylkill river, south of Conshohocken, and it is from this point to Westchester, some 20 miles westward, that the present remarks especially apply. Although in many portions exhibiting a distinct gneissic lamination, the rocks of this zone are held by the author to be of purely eruptive origin, consisting of syenites, acid gabbros, trap granulites, and other igneous rocks, often highly metamorphosed. It is the outer peripheral portion of this zone to which attention is here directed.

While the rocks are massive in the centre, this outer portion has been enormously compressed, folded and faulted, with the result of producing a tough, banded, porphyritic *fluxion gneiss*, identical with the 'milonite' of Lapworth or the 'sheared gneiss' of Peach and Horne. So perfect is the fluxion structure that the rock resembles a rhyolite. As in the 'banded granulite' of Lehmann, elongated felspar 'eyes' lie in flowing streams of biotite grains and broken quartz, the streams often parting and again meeting around the porphyritic 'eyes.' Occasional crystalline eyes of hornblende remain, but most of it has been converted into biotite.

A point of especial interest is that the felspar of the 'eyes' is quite colourless and free from inclusions, like the sanidine of recent lavas; while on the other hand the felspars of the inner and massive portions of the zone, out of which this outer portion has been reformed by pressure fluxion, are full of inclusions and have the 'dusty' appearance so common in ancient felspars. The fresh-looking felspar eyes have therefore very possibly been subsequently formed as the result of a *recrystallisation* of the old material under the influence of *pressure fluxion*. In similar manner the biotite has been made out of the old hornblende, garnets have been developed, and the quartz has been granulated and optically distorted by pressure.

The influence of pressure is also seen in certain Cambrian strata in the immediate vicinity, where a sandstone containing cylindrical casts of *Scolithus linearis*,

apparently identical with the 'pipe-rock' of north-western Scotland, has, like it, been compressed to such a degree that the vertical casts are flattened out and elongated in the direction of lamination to several times their original length. In the same sandstone quartz pebbles have been pulled out and flattened, while sericate has been largely developed along the cleavage planes. The pressure can be shown to have been directed mainly from the south-east.

2. The second locality is in the midst of the Laurentian area of Bucks County, and is known as Van Artsdalen's Quarry. A mass of crystalline limestone is here mingled with an eruptive diorite in such manner as to show that it had actually flowed like an igneous rock and had caught up inclusions. The results of extreme metamorphism are exhibited in the development in the limestone of graphite, ekebergite, and other minerals. The chemical changes and interchange of elements which might result from a loosening of molecular combinations under extreme pressure and their subsequent 'regelation' into new compounds were discussed as among the phenomena of mechanical metamorphism.

3. As an American instance of the conversion of an intrusive diabase dyke into amphibolite schist, analogous to the case recently described by Teall, a long narrow belt of sphene-bearing amphibolite schist in the city of Philadelphia was adduced. This belt, with distinctive mineralogical characters, cuts across the metamorphic mica schists of the region unconformably, and is believed by the author to be a highly metamorphosed intrusive dyke of Lower Silurian age. The original augite or diallage has been completely converted into fibrous hornblende, and the influence of pressure is shown in the perfectly laminated character of the schist, in the close foldings produced, and in the minute structure of the rock. Some interesting details of the latter having been photographed, diagrams constructed from these were exhibited. These showed that the rock was traversed by a parallel series of slips and crushings, and that about such lines of faulting and crushing there was a peculiar arrangement of the lines of hornblende crystals not very unlike the arrangement of iron filings about the poles of a magnet, such as could not be satisfactorily explained by any theory of aqueous deposition, but pointed to a lamination by pressure.

---

5. *On Slaty Cleavage and allied Rock Structures, with special reference to the Mechanical Theories of their Origin. By* ALFRED HARKER, *M.A., F.G.S.*—See Reports, p. 813.

---

6. *On Irish Metamorphic Rocks. By* G. HENRY KINAHAN, *M.R.I.A.*

This paper is an epitome of what is known as to the age of the Irish metamorphic rocks. The author gives ten Irish localities in which the rocks lithologically are more or less identical with the Laurentian rocks of America. Of each locality a short description is given, and where the age of the rocks is positively proved it is stated, while in the other cases the probable age is suggested. He also points out that while in some cases lithological characters are taken as a sure test of Laurentian age, in other cases they are ignored, by which means many rocks eminently lithologically similar to some of the Canadian rocks have been excluded from the so-called Irish Laurentians.

---

7. *On Rocks of Central Caithness. By* JOHN GUNN.

The term 'Central Caithness' is intended to embrace most of the parish of Halkirk and part of the parish of Watten.

The upper part of the parish of Halkirk is covered by drift gravel, underlying peat. At Loch More flagstones are presented. Below the lake may be traced the banks of what was once a great river. At Dirlot the rocks are sandstone, granite, gneiss, gneissic conglomerate, and limestone. At Dalmore the right bank of the Thurso is composed of boulder clay, the left of gravel. Here is seen a chain of

moraines, composed of granitic gravel and sand. At Tormsdale a vein of some cinder-like material occurs. The flagstones at Poll a' Chreagan are covered with freestone, as also at Dale Bridge on the right bank of the river. On the left the flags lie exposed in great tabular masses, overlying limestone. At the top of the Mill Pool are the remains of a natural dam. Below this pool a band of freestone once crossed the bed of the river. At Dale are shifting beds of gravel, and here the river is continually changing its course. Below Pollihour flags again appear, and opposite Scots Calder are banks of boulder clay, the boulders therein being very distinctly striated. Great masses of flagstone block up the bed of the stream at Gerston. At Halkirk the cliffs are coated with red ochre.

Granite is not visible at Dorrery, as has been stated by at least one writer, but it does not appear to lie at any great depth below the flags.

At Achanarras a curious fossil *Coccosteus* is found in a small slate quarry.

East from Spittal the angle at which the rocks dip gradually diminishes, and at Lanergill reaches its nearest approach to a dead level.

Drift gravel prevails in the neighbourhood of Halsary, and also down part of Strathbeg, where the banks of the ancient river may again be traced. Here the Dalmore moraines are continued.

No evidence of volcanic action can be gathered from an examination of the rocks of Central Caithness, but the district presents a fair field for the study of erosion by ice, air, and water.

---

8. *On some Rock Specimens from the Islands of the Fernando Noronha Group.* *By* Professor A. Renard, *LL.D., F.G.S.*

The rock specimens described in this communication were collected by J. G. Buchanan, Esq., during the voyage of the 'Challenger.' The islands have been described by Darwin in his 'Geological Observations on Volcanic Islands' (2nd edit., p. 27). The author, after having explained the geological structure, gave lithological descriptions of the chief types of the rocks, which may be referred to the phonolites (St. Michael's Mount). These phonolites are composed of sanidine, augite, nepheline, hornblende, magnetite, nosean, and titanite.

The rocks of Rat Island are basalts with nepheline. The constituent minerals are augite and olivine. The ground-mass is almost entirely composed of nepheline; biotite and apatite occur as accessory constituents. The little island known as Platform Island is also basaltic, with a doleritic texture. It is composed of labradorite, augite, olivine, magnetite, and biotite. This rock has undergone alterations.

---

9. *On the Average Density of Meteorites compared with that of the Earth.*[1] *By the* Rev. E. Hill, *M.A., F.G.S.*

The average density of the meteorites which fall on the earth is attempted to be calculated. Different methods described give as results 4·55, 4·58, 4·84, 5·71; the last value being influenced by the size of one particularly large metallic specimen. The average density of the earth is usually regarded as 5·6. Meteorites are samples of the materials of space, and a mass of them would aggregate into a body of density not widely differing from that of the earth. The densities of the other planets are not inconsistent with a like origin. Consequently any theory of the genesis of the earth from pre-existing materials involves a probability that an important part of its nucleus is metallic.

---

[1] *Geological Magazine*, 1885, p. 516.

TUESDAY, SEPTEMBER 15.

The following Papers and Reports were read:—

1. *Notes on a recent Examination of the Geology of East Central Africa. By* Professor HENRY DRUMMOND, *F.R.S.E., F.G.S.*

The district traversed included the littoral belt at the mouths of the Zambesi and Quilimane rivers, the region watered by the Shirè river from its source in Lake Nyassa to its terminus in the Zambesi, the Shirè highlands, and the western shore of Lake Shirwa, the rock-basin of Lake Nyassa, and the southern portion of the Nyassa-Tanganyika plateau. The first geological feature, on entering the country from the Zambesi, was an ancient coral-reef studded with sponges, which is exposed on the Qua-qua river above Mogurrumba. A few miles further inland sedimentary rocks are reached at Mopeia. A poor section occurs in the Zambesi above Shupanga, the beds consisting of red and yellow sandstones with intercalated marls and fine conglomerate. No organic remains were discovered, but the section may belong to the series found in a similar relation along almost the whole coast from the Cape to Zanzibar and northwards. The first hills reached, at Morumballa, consist of a very white quartzite. A hot spring occurs here, and one or two others are found on Lake Nyassa. Of the coal which Livingstone mentions on the Lower Shirè no trace was found after repeated examination. Dark rocks, of intrusive origin, occur at the locality. The coal on the western shore of Lake Nyassa, discovered by Mr. Rhodes, and described by Mr. James Stewart, C.E., was visited, and found to be of inferior quality, and existing only in small quantity. The seven-foot seam described by Stewart was really composed of thin beds of alternately carbonaceous and argillaceous matter.

The whole country from the Shirè a hundred miles above its junction with the Zambesi, the whole Shirè highlands, the western shore of Lake Nyassa, and the plateau between Nyassa and Tanganyika for half its length, consisted, with one interruption, of granite and gneiss. The character and texture of this formation persisted with remarkable uniformity throughout this immense region. The granite was an ordinary grey granite, composed of white, rarely pink, orthoclase; the mica of the biotite variety. Sometimes the gneiss persists over a large area, sometimes the granite, while frequently the two alternate within a limited space. Associated minerals were rare. Intrusive dykes of dolorite occur on the southern border of the Shirè highlands above Katunga. The only volcanic rocks met with were those already described by Mr. Joseph Thomson at the north end of Lake Nyassa. The only break in the granitic series occurs on the north-west shore of Nyassa, near Karonga. On the Rukuru river is found a well-marked series of stratified rocks, consisting of thin beds of very fine sandstone and shales, and occasional beds of limestone. After considerable search these beds were found to contain numerous fossils, including fish, mollusc, and plant remains. These fossils have not yet been examined, so that the age is uncertain, but the deposit is probably lacrustrine. Lake Shirwa is drying up rapidly, and there is evidence of a former and much larger Shirwa, which may have been confluent with Lake Nyassa. Lake Pomalombe is shoaling fast, and is the remains of a once greatly extended Lake Nyassa. Lake Nyassa lies in an immense rock-basin of granite and gneiss, the greatest depth being towards the high plateau on the northern end. After careful examination of this whole region no trace of glaciation, no boulder-clay, moraine, striation nor glaciated outline were anywhere to be detected.

2. *Report on the Rocks collected by H. W. Johnston, Esq., from the upper part of the Kilima-njaro Massif. By* Professor T. G. BONNEY, *D.Sc., LL.D., F.R.S., Pres.G.S.*—See Reports, p. 682.

---

3. *Some Results of the Crystallographic Study of Danburite. By* Max Schuster.

In studying the characters of the faces and the structure of the Danburite crystals found in Switzerland, the author had met with vicinal faces of a peculiar kind, for which he proposed the term 'transitional faces' ('Tschermak Min. Mittheil.' vi. 1884, p. 511). Attention was called to the fact that these faces are easily affected by those causes which produce an unequal development of faces otherwise symmetrically disposed, and an illustration was given of the way in which their indices are numerically related to those of the principal faces of the crystal.

---

4. *American Evidences of Eocene Mammals of the 'Plastic Clay' Period. By* Sir Richard Owen, *K.C.B., F.R.S., F.G.S.*

In the year 1843 a fragment of a lower jaw with one entire molar of a mammal was dredged up off the Essex coast. A canine tooth of the same was found in a well-sinking near Camberwell, in piercing the 'plastic clay.' The author had described the above as belonging to an animal of the Lophiodont family, and proposed for it the generic name Coryphodon. Shortly afterwards De Blainville had noticed certain fossils as 'probably Coryphodont,' but had referred them to *Lophiodon anthracotherium.* Ten years later Professor Hebert had recognised two species of *Coryphodon* in the plastic clay of France. Explorations by Leidy, Marsh, and Hayden, in the Mauvaises Terres of Nebraska had led to the discovery of a large hoofed mammal allied to *Coryphodon*, to which the name *Titanotherium* had been given; and Professor Cope has now recognised, from Evanstown, Wyoming, seven species of *Coryphodon.* From these materials, which have been rendered accessible to European palæontologists by the superb volume of reports recently issued by the United States Government, the author is enabled to give a general description of this family of hoofed mammals of large size, which flourished in early eocene times. To the details of this the major part of the paper is devoted.

8. *Some Results of a detailed Survey of the Old Coast-lines near Trondhjem, Norway. By* Hugh Miller, *F.G.S.*

During a short visit to Norway in October 1884, it appeared to the author that the best way to help to a solution the vexed questions connected with the coast-terracing of Norway was to execute a careful survey of a few square miles of some suitable coast region upon a sufficiently large scale. The neighbourhood of Trondhjem is remarkably well suited to this purpose. The map employed was partly a municipal chart on the scale of $\frac{1}{10000}$, and partly an enlargement of the Ordnance Map. The limit of all the terraces and marine deposits is the famous 'strand line' west of the town, a double range of old-coast cliff cut in the rock of the mountain side. Its upper line is 580 feet above the sea,[1] and answers

[1] R. Chambers's measurement of the lower line in 1849 was 522 feet by level and staff. To this is added Professor Mohn's estimate (58 feet) of the interval between the two. The latter proves to be excessive.

to the 'marine limit' over Norway generally. Numbers of level terrace-lines have been incised—chiefly in greenish clays, like brick-clays—all along the arable slopes east of the town between this rock-terrace and the sea. Above the Bay of Leangen, two miles east of town and river, and far beyond all erosive influence of the latter, thirty of these lines were mapped one above another in the first 300 feet of ascent, a distance of one and a half mile. Many of these are small but extremely distinct, the earthy clays being well suited to retain sharp impressions of successive sea-margins, which these unequivocally are. The present coast-line, neatly etched out by the waves in Trondhjem and Leangen bays, is the key to these tiers of older ones. It also resembles them in having made little or no impression where the coast becomes rocky, the lines of incision in both cases stopping short at once when they reach the harder material. The old coast-lines are most numerous in well-sheltered positions. Thus a single pair of large terraces in an exposed situation east from Christiansten, where they face the open water of the fjord and the prevalent north-westerly storms, is represented in the recess above Leangen Bay by ten or twelve. The same fact is brought out on rising from this recess to the higher and more exposed ground. Thus, while thirty-three or thirty-four terraces are mapped below 350 feet (approximate) elevation, only nine or ten appear between that level and the rock-terraces of the upper marine limit, the numerical average height of each terrace thus rising by more than a half. In recesses of the coast further east, but beyond the map, these upper terraces seem to be preserved in considerably greater numbers. The number actually mapped was forty-three, or with the two rock-terraces, forty-five. The largest number of terraces hitherto described at any one place in Norway seems to have been less than half that number.

Some of the general conclusions of the author are as follows:—(1) These terraces are all post-glacial, *i.e.* formed subsequent to the rock-glaciation of the district. This is confirmed by the condition of the high coast-cliff, which has been cut in ice-rounded rock, but is not itself glaciated. It appears, however, from the fauna of the raised shell-banks of the country (as worked out by Sars and Kjerulf), in which recent shells do not rise above 380 feet, that the seas of the upper levels were still glacial; and, though the Trondhjem fjord was free from land-ice, other deeper fjords and higher coasts may still have had glaciers coming into conflict with the sea, and producing the glaciated rock-terraces described elsewhere by Sexe. All the evidence obtained discountenances Sexe's view that these rock-terraces were cut out by glaciers, as well as Carl Petersen's that they were rasped out by floating ice coasting the shores. On the clay terraces coast-ice has left no more sign of its presence than the winter freezing of our British rivers leaves upon our river terraces. (2) If the country was upraised by a succession of elevatory jerks, as supposed by most geologists from Keilhau downwards, most of these would seem to have been small—much smaller, at least, than is supposed by Kjerulf. It is improbable that even Leangen Bay was secluded enough to contain a record of all the original coast-lines. The longer pauses and greater storms may have effaced an unknown number of them by a process of excision exemplified in all its stages by the map. It is hard to say, in fact, where the subdivision, if it could be fully traced out, would end. The smaller terraces remind the eye of the incised lines and little planes engraved on the sandbanks bordering the rivers after a flood, where there is no periodicity in the subsidence of the waters. (3) The preservation or excision of the terraces thus seems to depend as much upon local circumstances —exposure to storms, resistance of coast-line, &c.—as upon anything else. It is impossible at present to predicate which of them shall in any given place remain. Whether elevation by jerks, therefore, be postulated or not, all hope of correlating these terraces throughout the country must be deferred until their heights have been accurately determined by level. The measurements hitherto made, not even excepting those of Professors Kjerulf and Mohn, are probably inadequate for the purpose. This observation seems to apply also to the terraces graven in rock. In their aneroid measurements of the upper strand-line at Trondhjem these observers differ by fifty-five feet. (5) On entering the mouth of the Trondhjem Valley the terraces come under an influence other than that of the sea-waves. The valley was

worked out, in deposits partly levelled out by the sea, according to the laws of river terracing under the accelerating influences of a falling sea-level. The processes of automatic river terracing are beautifully exemplified within the district mapped, in the deep lobe-shaped curve of the river just before it enters the sea. The terraces have been added one after another to the point of the lobe of land thus surrounded, which is known as Öen.

---

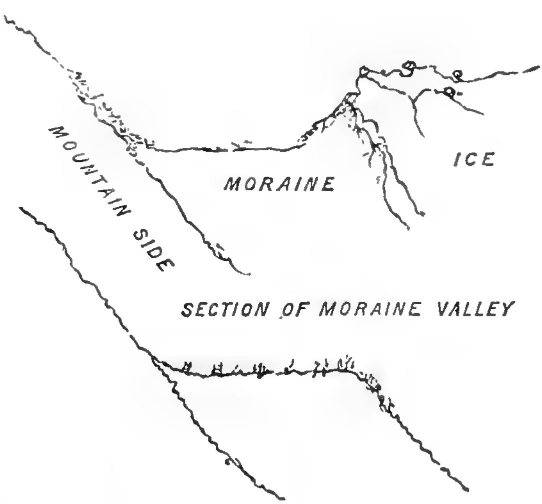
9. *The Parallel Roads of Lochaber.* By JAMES MELVIN.

These singular-looking lines, resembling in the distance water-races or roads traced along the mountain sides of three glens in Lochaber, have hitherto proved a puzzle to the learned and unlearned.

The theories submitted to account for their origin are open to grave objections, and all of them, save that of their being the margins of lakes held in by the ice of glaciers which flowed down the corries from the lofty mountains, have generally been given up.

This last, when carefully considered and looked at from different points of view in the district itself, seems open to serious objections. In the first place, it necessitates the existence of great glaciers in the lower portions of the glens with the water of lakes in the higher. It further necessitates the cessation of certain of these glaciers in Glen Spean, over perhaps nine-tenths of the district formerly producing them, and their retention in one-ninth of the surface from which they had previously flowed.

TASMAN VALLEY, MOUNT COOK, NEW ZEALAND.



SECTION AND TERRACE IN LOWER VALLEY.

(Method by which the Glacier forms Terraces somewhat similar, perhaps exactly similar, to those of the Lower Tasman Valley.—Page 200, Green's 'High Alps of Queensland.')

Those corries and opener glens, such as the Gulbein, the Treig, and the Laire which it is said supplied the ice-barriers when the upper roads in Glen Roy were being formed, issuing as they do from 100 square miles of mountain country, the peaks of which rise to 3,658 feet, according to the requirements of the ice-dam supporters, must become barren. These glaciers must shrink up, without any other reason being assigned than the necessity of their doing so to enable the supporters of the ice-dam to prove their case.

While this large extent of previously ice-producing country ceases to furnish any more ice to the Spean valley, one solitary glen, the Cour, drawing a supply from about eleven square miles, is allowed to maintain all its original ice-producing

power, and to form the great dam stretching more than four miles across the valley of the Spean, though aided on the other side of the Caledonian Canal by the ice from the glen.

The country which fed this glacier of the Cour consists of about eleven square miles of surface, with a peak 4,000 feet high. It does not seem to possess such a position so that a great glacier should continue to flow from it when the other glens adjoining had lost their glacier-producing power.

The drainage outlet of 700 miles of mountainous country within which the roads are is at Corron Ferry. It is narrow, contracted, and the ice would be jammed back during the intense period of glaciation, and a portion forced over the Col in Glen Spean into the Spey.

The roads consist of the usual glacial stuff from the hill sides. Neither sea shore nor lake shingle shells, water sorted sands nor silts, are met with. Some material run from the hill sides before vegetation covered the surface may be seen.

What, then, were the causes which led to the formation of those roads? The resting of the ice of the glaciers at certain levels after the great glaciation ceased, and when the ice in these glens of Gloy, Roy, and Spean found its way outward by the lowest level. The lateral moraines so formed when the supply of ice was sufficient to maintain their movement seaward are now the roads.

Thus, in Glen Gloy, No. 1, the road and several somewhat similar terraces, as shown in Sir Henry James Vance's work on the roads, would be formed by the ice after it had ceased to flow over the *col* into Glen Roy.

No. 2, in Glen Roy, after the ice ceased to flow into the Spey.

No. 3, after no more ice flowed into Glen Spean from Glen Roy, by the *col* Glen Glaister; also several other shelves or terraces seen in the district.

And No. 4, in Glens Roy and Spean, would be forming so long as the Gulbein, the Treig, the Laire, and the Cour supplied sufficient quantity of ice to maintain the glaciers in these valleys at the levels where the roads now are.

---

10. *Further Evidence of the Extension of the Ice in the North Sea during the Glacial Period. By* B. N. PEACH, *F.R.S.E.*, *and* J. HORNE, *F.R.S.E.*

The authors briefly summarised at the outset the results of their investigations regarding the glacial phenomena of Shetland and Orkney, which point to the conclusion that they were glaciated by land ice that moved from the North Sea towards the Atlantic, while at a later period they were subjected to a purely local glaciation.

They then proceeded to call attention to certain observations of Dr. Traill, on the glacial phenomena of North Ronaldshay, which is situated at the extreme north-east corner of the Orcadian group, and, like the other isles, is composed of Old Red Sandstone and mainly of the characteristic flagstone series. In the red boulder clay an assemblage of stones foreign to Orkney was obtained, consisting of diorite, gabbro, granite with various kinds of metamorphic foliated rocks, volcanic tuff like that of the Ochils, chalk and chalk flints. With few exceptions these foreign blocks might have been derived from the basin of the Moray Firth and the surrounding high ground. Numerous smoothed and striated fragments of marine shells were also met with in the boulder clay. These phenomena are identical with those found in the boulder clay of the other Orcadian islands, and they point to the conclusion that the northern limits of Orkney must have been glaciated by ice from Scotland moving in a westerly direction.

Reference was also made to the results obtained by Dr. John Murray while exploring the 'Wyville Thomson Ridge,' in the summers of 1880 and 1882, the surface of which seems to be covered with boulder clay or moraine matter. The stones dredged from the northern part of the ridge consist of metamorphic rocks and Old Red Sandstone, which might have been derived from Shetland, while more than half of the blocks from the south end are composed of flagstones of the Orkney and Caithness flagstone series. From the distribution of the boulders, some of which are well striated, it is evident that the ice must have moved west-

wards across the submerged platform of which Shetland and Orkney are the surviving relics.

11. *Recent Advances in West Lothian Geology.*[1] *By* H. M. Cadell, *B.Sc.*

Until after the discovery of the oil shales about twenty-five years ago, the relations of the Lower Carboniferous rocks of West Lothian were very imperfectly understood. Nothing of importance has been written on the geology of the eastern part of the county since 1861, when the Explanatory Memoir accompanying the Geological Survey map of the district was published. Since then much new evidence relating to the upper part of the Calciferous Sandstone series has accumulated.

The Calciferous Sandstone or Lower Carboniferous series, as developed along the great anticline of Midlothian, consists at the base of a series of red sandstones with thin shales and marls, and occasional interbedded volcanic rocks at the top. Above the red rocks come the white and gray sandstones of Granton and Craigleith, which are in turn overlain by the black shales of Wardie, and the sandstones and shales of Hailes and Redhall. Each of these two great divisions has, according to the measurements of Mr. John Henderson, a thickness of over 3,000 feet.

The oil shale group, which comes next, includes the 'Cement stone group,' apparently begins with the Pumpherston shale, situated some 780 feet below the Burdiehouse limestone. It occupies the remainder of the Calciferous Sandstone series and has in West Lothian a thickness of about 3,100 feet, so that the whole thickness of Lower Carboniferous rocks in West Lothian probably exceeds 9,000 feet. The Dunnet shale is the lowest member of the upper group of oil shales, and lies about 400 feet above the Burdiehouse or Camps limestone. About 450 feet higher up comes the Broxburn shale, which is perhaps the most important of the West Lothian oil shales. The strata intervening between the Dunnet and Pumpherston shales, and including the limestone, are chiefly argillaceous shales with thin calcareous bands and occasional sandstones. Above the Dunnet shale they become more arenaceous, and thick sandstone beds are developed, one of which has long been quarried at Binny, near Uphall, for building and ornamental purposes. The Broxburn shale, which is several fathoms above the Binny sandstone, forms a well-marked horizon, as it underlies a group of marls and thin limestone bands varying in thickness from 80 to 270 feet. This calcareous zone, locally known as the 'Broxburn Marl,' passes under the Fells shale, above which comes another series of sandstone beds about 240 feet thick, which underlie the Houston coal. This is perhaps the oldest coal seam in Britain, as in the Broxburn district it is situated about 1,000 feet below the base of the Carboniferous Limestone series. The Houston coal is covered by about 200 feet of pale green and red amorphous marl, sometimes containing pieces of volcanic ash, and is apparently a fine volcanic mudstone. A thin coal seam and some oil shale occur just above the 'Houston marl,' and two other oil shales have been worked still higher up, the highest of which—the Raeburn's shale—is some 400 feet below the Carboniferous limestone.

The oil shales and underlying parts of the Calciferous Sandstone series have no regular strike, but are bent about into troughs, domes, and anticlines, and are dislocated by large faults, besides which there is great irregularity in the thickness and character of the rocks, so that to work out the geological structure of the ground without the aid of mining information would be an impossible task.

The oil shales are simply fine clay shales impregnated with hydrocarbon, and when distilled yield on an average 30 gallons of crude oil per ton, and enough ammonia to yield from 10 to 45 lbs. ammonia sulphate. They have evidently been deposited extremely slowly in a large gradually-subsiding estuarine or fresh water area, inhabited by numerous fishes, lamellibranchs, and small crustaceans, whose remains, along with those of plants, were constantly being deposited on the sea

[1] Communicated by permission of the Director-General of the Geological Survey.

floor along with a comparatively small proportion of muddy sediment. Oil shale is easily recognised in the field by its resistance to the disintegrating action of the weather, and by the facility with which it can be cut and curled up with the point of a knife.

The Carboniferous Limestone series, whose thickness is about 2,000 feet, is divisible into three main groups: a basal group with sandstone shales, thin limestones, and one coal seam at the bottom; a central group with coal seams and no limestones; and an upper group with three limestones, sandstones, and a few thin coal seams. At Bo'ness, on the Firth of Forth, north of Linlithgow, the coal-bearing group has a thickness of about 900 feet, and is subdivided by a central zone of interbedded basalt rocks 330 feet in thickness, into an upper and a lower series, each containing four workable seams of coal and a seam of ironstone.

The oldest member of the interesting volcanic series of West Lothian seems to be a bed of tuff resting on the Houston coal near Queensferry, from the denudation of which the Houston marl here situated a few fathoms higher up, may have been derived. Volcanic activity was rife during almost the whole of the Carboniferous limestone period, especially in the district south of Linlithgow, where the great bank of interbedded basalt rocks forming the Bathgate and Torphichen Hills was poured forth. These old lavas extend from beneath the lowest marine limestone in almost uninterrupted succession to near the top of the limestone series, and have a total thickness of more than 2,000 feet. On each side the volcanic rocks thin out and become replaced by sedimentary strata and coal seams in the Bo'ness and Bathgate coalfields. 'Necks' of diabase and basalt tuff, piercing the lower parts of the Carboniferous Limestone and the Calciferous Sandstone strata to the east of Linlithgow are numerous, and have probably been connected with interbedded rocks on higher horizons now removed by denudation. The largest, forming the Tor Hill at Ecclesmachan, has a major diameter of about 600 yards, and cuts through the Houston coal and underlying shales.

---

12. *Barium Sulphate as a Cementing Material in Sandstone.* *By* Professor Frank Clowes, *D.Sc.*

Bischof mentions instances of foreign sandstones in which the material which cements the sand grains together is barium sulphate; but it appears that up to the present time no such sandstone has been discovered in the United Kingdom. Having learned from my colleague, Professor Blake, that opinions of geologists differ regarding the calcareous nature of certain sandstone beds in the neighbourhood of Nottingham, I undertook to ascertain the chemical composition of this sandstone. At the spot in question the sandstone appears as two conical hills known as Stapleford and Bramcote Hills, and as a pillar of rock about twenty feet in height known as the Hemlock Stone. The Hemlock Stone stands in the space intervening between the hills, and is capped so as to be somewhat mushroom shaped. In company with Professor Blake I procured specimens of the sandstone at different levels of the hills and of the stone. One of the specimens was subjected to careful chemical analysis by two senior students in my laboratory at the University College, Nottingham; they find the very high amount of 30 per cent. of barium sulphate in the sandstone. I have also recently detected the presence of much barium sulphate in all the sandstone specimens from both the hills and the Hemlock Stone, while some of the lower beds also contain calcium carbonate. The percentage proportion of barium sulphate present in the samples is at present being determined with care.

The results of the chemical examination of this sandstone thus far show that geologists who took samples from the lower part of the Hemlock Stone would consider the sandstone to be calcareous after applying the usual acid test, whilst others who examined the cap of the stone would find no calcareous matter, and would fail to detect the barium sulphate which is the true cementing material. It seems probable that the protective cap of the pillar owes its comparative permanence against weathering action to the presence of this almost insoluble sulphate in large proportions.

In some of the sandstones which have been examined the barium sulphate is very unequally distributed, forming either a network or a series of small patches more or less spherical in shape. In such sandstone the sand grains which are uncemented by the sulphate are loose and readily separated from one another. Hence, when subjected to weathering, it presents a honeycombed or mammillated appearance. In one bed which caps the Bramcote Hill, and which is usually described as the pebble bed, the removal of the intervening loose sand leaves little cemented masses about the size of a hazel-nut: these, however, are not pebbles in the ordinary sense of the word, but are merely sand grains cemented by the sulphate.

I have attempted to trace some evidence of the way in which the barium sulphate has been introduced into the sand bed. It may have been deposited originally with the sand grains; but if this is its origin it has undergone physical change, since it now presents a compact crystallised mass. It seems certain, therefore, that it has either been originally deposited from solution, or has been rendered crystalline by the slow percolation of a solvent liquid through the sedimentary deposit. A third method seems possible. Bischof carried out experimentally the conversion of barium carbonate into sulphate by the action upon it of calcium sulphate solution; this double decomposition would produce barium sulphate together with calcium carbonate, and precisely such a mixture is found in the lower beds of the Hemlock Stone.

As regards the possibility of barium sulphate existing in solution, as was supposed in an earlier part of this communication, I have recently examined a stalactite which consists almost wholly of barium sulphate; and specimens of little sand masses bound together by barium sulphate in large crystals have also come into my hands. A solvent has in any case been present at some time, to cause the barium sulphate of these sandstones to assume the crystalline condition, since Bischof shows that the sulphate cannot be crystallised by fusion.

---

13. *Notes on Fuller's Earth and its applications.* *By* A. C. G. Cameron.

The author in this paper describes Fuller's earth, its properties, and varieties. In its more concrete signification Fuller's earth is the name applied to the red loamy stratum overlying the Inferior Oolite in the south of England. But its more general application is of economic and not of geological significance. He mentions that that dug from near the base of the Bedfordshire Greensand is of superior quality, and characterises it as a purifier of water. Fuller's earth in general is mentioned as a fine clay, less used now than formerly for cloth dressing. Considerable quantities are, however, still dug from the Lower Greensand and Oolites of the south of England for fulling and general cleansing purposes. Aspley Heath, on the brow of the Greensand escarpment, Woburn, Bedfordshire, is described as the locality where operations are presently going on for the purpose of procuring varieties of Fuller's earth. Cylindrical holes, called 'earth wells,' are dug deep in the soft yellow sands, sometimes rocky with ferruginous lumps and thin carstone, in order to reach the Fuller's earth, which lies far down as a tabular and nearly horizontal mass, separated by not many feet of sand from the Oxford clay. Nearly two hundred years ago the pits were at Wavendon, an outlier of the Greensand, amongst the Oxford clay. A description of the beds is given as presently existing. Although superficially considered as all one earth, the substance is of three distinct kinds, which are mentioned, and their local names given. Allusions are made to substances dug in Warwickshire, the Isle of Skye, and Maxton Roxburghshire, as substitutes for Fuller's earth, and a letter is quoted from a resident in Maxton bearing on this subject. The action of Fuller's earth on peaty or otherwise discoloured water is described, with special allusion to, and description of, the 'Natural Mineral Water' at Flitwick, Bedfordshire. Conflicting opinions as to this mineral water are given, with analysis supplied by Drs. Piesse and Johnstone, public analysts, London, and one published by a Professor White. Results of various experiments are stated, showing the efficacy of Bedfordshire Fuller's earth as a filtering medium. The author is not prepared to say whether these filtra-

tions are mechanical, or are due partly to chemical action, as this question is still undetermined. He suggests that Fuller's earth might be advantageously placed with other materials in filter beds, or otherwise used as a water purifier on a large scale.

WEDNESDAY, SEPTEMBER 16.

The following Papers and Report were read:—

1. *On the Glacial Deposits at Montrose.* *By* Dr. HOWDEN.

These consist in order of age, first, of the non-fossiliferous boulder clay, derived chiefly from the denudation of the great conglomerate. Second, a glacial marine clay, containing the remains of the Arctic seal (*Phœa hirta*), Arctic birds, fishes, star-fishes, mollusca, and foraminifera, besides pieces of ice borne chalk, flint, coal, and other rocks foreign to the district. Third, deposits of peat, in which are found remains of the reindeer, trees, and bog plants, including the buckbean; a grain of the common barley was also got in this peat. Fourth, a thick bed of estuary, or scrobicularia silt, containing shells of species found living in the present estuary basin of the South Esk. In this deposit at the Redfield Railway cutting, nine feet below the surface, the skull of an ox, *Bos longifrons*, was found beneath an undisturbed deposit of sand and coarse clay. Fifth, a bed of apparently glacial coarse clay. These deposits terminate on a great ridge or storm beach consisting of pebbles and small boulders derived from the boulder clay. This ridge divides the town of Montrose into two halves, known to builders as the clay half and the sand half. In the sand half, slightly above the level of the present sea beach, marine shells are found of species now living on the coast, but a much larger size. The diagrams and specimens exhibited indicated repeated alternation of climate and level since the earlier glacial period.

---

2. *Notes on the Rocks of St. Kilda.* *By* ALEXANDER ROSS, *F.G.S.*

On a visit to St. Kilda in 1884 I collected a few specimens of the rocks of which the island is composed, and which are now presented for inspection to the members of the British Association.

The island has been described as being in the form of the letter H, the northern limb being represented by Connacher and Oschival, and the southern by the Mullach More. These limbs are connected by a ridge which forms the cross bar of the H, and divides the north from the south bay. The latter bay is nearly circular, the hills sloping in all directions and forming an almost perfect amphitheatre.

The land rises to a considerable height on the west side of the island, which is bounded by cliffs from 800 to 1,000 feet high.

The island is composed of granite and gabbros, which meet in a line running from the west side of the village at the south bay to the centre of the glen at north bay. The portion to the north of this line is composed entirely of cream-coloured granite, while that to the south consists of greenstones and gabbros.

In the course of a walk extending from the landing-place on the north side, along the summit of Oschival and Connacher down into the valley at north bay, and along the north shoulder of Mullach More back to the south bay, I picked up the specimens now exhibited.

Passing along the top of the ridge between Oschival and Connacher and over the top of the latter, I found as I began to descend towards the line of junction the granites becoming finer grained and more compact. Along the line of junction the change is very marked, and on crossing it, we come on the gabbros and greenstones, on the southern side of the glen. Some of the specimens illustrate this walk.

Specimens were also taken from the bare slopes and precipices near the sea, where the junction can be more clearly seen.

The specimens picked up along the line of junction consisted of granite studded throughout with angular fragments of basalt, which fact appears to indicate the posteriority of the granite.

Taken by themselves these specimens would seem to point to the conclusion that the granite had been erupted at a later date than the gabbros, and that the molten granite had included the shattered fragments of an older rock in it.

The main question which the specimens would appear to suggest is—'What are the respective ages of the granites and gabbros?'

The specimens in my opinion appear to point to the posteriority of the granite, and one specimen shows a vein of granite piercing the basalt.

3. *Eleventh Report on the Circulation of Underground Waters in the Permeable Formations of England and Wales, and the Quantity and Character of the Water supplied to various Towns and Districts from these Formations.*—See Reports, p. 380.

---

4. *On Deep Borings at Chatham: a Contribution to the Deep-seated Geology of the London Basin. By* W. WHITAKER, *B.A., F.G.S., Assoc.Inst.C.E.*

A few years ago the Admiralty made a boring in the Chatham Dockyard Extension, to the depth of 903½ feet, just reaching the Lower Greensand, and in 1883-84 followed this by another boring, near by, to increase the supply, which has led to an unexpected result. After passing through 27 feet of Alluvium and Tertiary beds, 682 of Chalk, and 193 of Gault, the Lower Greensand was again reached; but, on continuing the boring, was found to be only 41 feet thick, when it was succeeded by a stiff clay, which, from its fossils, is found to be Oxford Clay, a formation not before known to occur in Kent.

At its outcrop, about seven miles to the south, the Lower Greensand is 200 feet thick, and is succeeded, a little further south, by the Weald Clay, there 600 feet thick. Not only, however, has this 600 feet of clay wholly disappeared, but also the whole of the next underlying set of deposits, the Hastings Beds, which crop out everywhere from beneath the Weald Clay, and are also some hundreds of feet thick.

More than this, the Purbeck Beds, which underlie the Hastings Beds near Battle, are absent, and also the Portlandian, Kimmeridge Clay, Corallian, &c., beds which have been proved above Oxford Clay in the Subwealden Boring, to the great thickness of over 1,600 feet.

We are therefore faced with a great northerly thinning of the beds below the Gault, a fact agreeing in the main with the evidence given of late years by various deep wells in and near London.

Three other deep borings have been made or are being made near Chatham, all of which have passed through the Chalk into the Gault, and one has gained a supply from the sand beneath.

The practical bearing of the Chatham section is, however, to enforce the danger of counting on getting large supplies of water in the London Basin from the Lower Greensand, by means of deep borings at any great distance from its outcrop.

Even if Lower Greensand occur at all in such places, it will probably be in reduced thickness, and therefore with reduced water-capacity.

---

5. *On the Waterworks at Goldstone Road, Brighton. By* W. WHITAKER, *B.A., F.G.S., Assoc.Inst.C.E.*

Notes of a visit underground in December 1884, when the water was pumped down for extending the galleries.

These works are perhaps the best example of the right way of getting a very

large supply of water from the Chalk, galleries being driven (in one case to the length of 800 feet) at about low-water level, so as to cut the fissures and intercept the water on its way to the sea.

The whole of the works (shafts and galleries) are in the White Chalk, with but few flints in the bedding-planes, but with many oblique layers along joint-planes. The supply comes chiefly from a few powerful springs, and, though small contributions issue between these, it is noteworthy how far a tunnel has sometimes been driven before reaching a fissure of large yield. Under these circumstances borings, or even shafts, might have failed to yield a large supply.

The roof of the north-eastern gallery is throughout of one bed, rarely needing support, a thin brittle layer of flint at its base being cleared away.

Section D.—BIOLOGY.

President of the Section—Professor W. C. McIntosh, M.D., LL.D., F.R.S.L. & E., F.L.S.

THURSDAY, SEPTEMBER 10.

The President delivered the following Address:—

I have selected the subject of the phosphorescence of marine animals for a few remarks on the present occasion—the theme, perhaps, being the more appropriate from its congenial local surroundings; for, like St. Andrews, Aberdeen is an

'old University town
Looking out on the cold North sea.'

A phenomenon so striking as the emission of light by marine organisms could not fail to have attracted notice from very early times, both in the case of navigators and those who gave their attention in a more systematic manner to the study of nature. Accordingly we find that the literature of the subject is both varied and extensive—so much so, indeed, that it is impossible on the present occasion to give more than a very brief outline of its leading features. This is a subject of less moment, however, since the great microscopist, Ehrenberg, in his treatise, 'Das Leuchten des Meeres,' published by the Berlin Academy in 1835, has given a very full account of the early literature on phosphorescence, both in marine and terrestrial animals, no less than 436 authors being quoted. The limitation just mentioned is therefore sufficiently warranted.

Though it is in the warmer seas of the globe that phosphorescence is observed in its most remarkable forms—as for instance the sheets of white light caused by *Noctiluca*, and the vividly luminous bars of *Pyrosoma*—yet it is a feature which the British zoologist need not leave his native waters to see both in beauty and perfection. Many luminous animals occur between tide-marks, and even the stunted seaweeds near the line of high-water everywhere sparkle with a multitude of brilliant points. As a ship or boat passes through the calm surface of the sea in summer and autumn, the wavelets gleam with phosphorescent points, or are crested with light; while the observer, leaning over the stern, can watch the long trail of luminous water behind the ship, from the brightly sparkling and seething mass at the screw to the faint glimmer in the distance. On the southern and western shores, again, every stroke of the oar causes a luminous eddy, and some of the smaller forms are lifted by the blade and scintillate brightly as they roll into the water. The dredge and trawl likewise produce, both in the shallower and deeper parts of our seas, many luminous types of great interest and beauty.

I shall, in the first instance, glance at the various groups of marine animals which possess the property of phosphorescence, and thereafter make some general remarks on the subject. It is found then that this feature is possessed by certain members of the Protozoa, and by the following groups of the Metazoa, viz.: Cœlenterates, Echinoderms, Worms, Rotifers, Crustaceans, Molluscoids, Mollusks, and Fishes.

About the middle of last century Baster found that at least three species of

what he called microscopic animalcula,[1] apparently Infusoria, were phosphorescent; and fully half a century later Pfaff noticed that the luminosity of the sea at Kiel was due to certain members of the group just mentioned. Subsequently both Michaelis and Ehrenberg met with phosphorescent Infusoria in the Baltic, the latter describing them as species of *Peridinium* (now *Ceratium*), and *Prorocentrum*. The same fact, associated with the absence of *Noctiluca* at Kiel, has again more recently been brought forward by Stein. In our own seas I have been especially struck with this feature in July and August, the whole surface of the sea along the eastern shores of England and Scotland teeming with *Ceratium* and *Peridinium*, besides other Infusoria, which form a greenish scum on the interior of tow-nets in inshore water, and for many miles seaward. As the waves curl from the sides of the boat in quiet water, the crest of each sparkles with multitudes of luminous points, which gleam for a moment as the ripple stretches outward and then disappear; or still more vividly when the plunging vessel sends the sparkling spray all around the bow. If on removing the tow-net from such water at night it is suddenly jerked, the whole interior is beautifully lit up with a luminous lining, which glows brightly for a few seconds and then fades. I have been unable, nevertheless, to satisfy myself as to the phosphorescence of isolated examples of *Ceratium*, and Mr. Murray (who is inclined to follow Klebs in considering them Algæ) tells me that he has not been more successful.

The most conspicuous member of the first group (viz., the Protozoa), however, is *Noctiluca*, which for a long time has been associated with luminosity in many seas. The minute size of this little transparent gelatinous sphere, which ranges from $\frac{1}{5}$ to $\frac{1}{3}$ of a millimètre, probably gave origin to some of the ancient views that the phosphorescence of the sea originated from the water, and not from any visible organisms. Amongst the first who clearly made known the relationship of this minute body to the phenomenon we are examining, was M. Rigaut, a French naval surgeon, who examined it off various parts of the French coast as well as off the Antilles, and pointed out in a memoir communicated to the Academy, that the luminosity of the sea was caused by an immense number of what he termed little spherical polyps, about a quarter of a line in diameter.[2] The observations of this acute French surgeon were followed up by many subsequent authors, amongst whom may be mentioned Baker, Martin Slabber, Abbé Dicquemare, Suriray, Macartney, and Baird; while in more recent times Verhaege, De Quatrefages, and Giglioli have specially studied the phosphorescence of the sea caused by *Noctiluca*. The light given out by this form is occasionally spread over a large area, and is often evident along the margin of the beach, where the broad belts of Noctilucæ gleam in the broken water. It is not uncommon in summer on the southern shores of Britain, while it is rare in the northern; but it stretches into most of the great oceans, and is the cause of that diffused and silvery phosphorescence so well known to voyagers in the warmer seas. At Ostend, Verhaege found the maximum number in a given quantity of water in the warm months, few or none appearing in the winter. The observations of De Quatrefages [3] were made on the shores of France as well as those of Sicily, for he accompanied the distinguished Professor Henri Milne-Edwards (whose loss science has had so recently to deplore) on his celebrated 'Voyage en Sicile,' and they were more extensive than those of the previous author. He attributes the emission of the clear bluish light in quiet water, or the white light with greenish or bluish touches in broken water, to any physical agent which produces contraction, the scintillations arising from the rupture and rapid contraction of the protoplasmic filaments in the interior. Thus, like Verhaege and others, he found no special luminous organ. Moreover, Ehrenberg and De Quatrefages observed that the light emitted by *Noctiluca*, though apparently uniform under a lens, was broken up into a number of minute scintillations when highly magnified. Mr. Sorby, in examining the light of this form,

[3] 'Observations sur les Noctiluques,' *Ann. des sc. nat.* 3e Série, Zool., tom. xiv. p. 226.

has been unable to obtain satisfactory spectroscopic results, apparently from its feebleness.

Besides *Noctiluca*, which was chiefly met with in inshore water, Mr. Murray, of the 'Challenger,' describes various species of *Pyrocystis*,[1] a closely allied form, and indeed some of which have been thought to be identical with the former. They abound in the open sea, and are the chief causes of its phosphorescence in the tropical and subtropical oceans. The light is stated to proceed from the nucleus, and in this respect it diverges from that observed by De Quatrefages in *Noctiluca*. When shaken in a glass, they give out, Sir Wyville Thomson observes,[2] the uniform soft light of an illuminated ground-glass globe.

Dr. Giglioli, during the voyage of the Italian frigate 'Magenta,' mentions[3] that another division of the Protozoa, viz., the Radiolaria, show phosphorescent properties. In the Pacific the genera *Thalassicolla, Collozoum,* and *Sphærozoum,* shone with an intermittent greenish light. It is possible that Dr. Baird,[4] in his earlier paper, refers to the same group when describing an unknown phosphorescent pelagic organism.

No group of marine animals is more prominent in regard to phosphorescence than the Cælenterates. The Hydroida are familiar examples,[5] and, as Mr. Hincks observes, none excels the common *Obelia geniculata,* which forms pigmy forests on the broad blades of Laminariæ all round our shores. In the fresh specimen a touch during summer causes a large number of luminous points to appear on the zoophytes, the stems most irritated emitting beautiful flashes, which glitter like faintly-dotted lines of fire, the points not being harshly separated, but blending into each other, while the shock imparted by the instrument detaches the minute medusoids, which scintillate upward from the parent stem to the summit of the water. Mere blowing on the surface in July, where Laminariæ abound, suffices to produce the emission of light from the pelagic buds. Moreover, these minute bodies, along with the various species of *Ceratium* and minute larval forms of diverse kinds, are sometimes swept by the gales landward, and cause phosphorescence where least expected. In the same manner Vaughan Thompson[6] found luminous patches on the masts and windward yard-arms on board ship, and they gradually mounted upward as the gale increased. Many of the free gonosomes of the Hydroids are as luminous as the polypites, and indeed have been described by some of the older naturalists as one of the main causes of the luminosity of the ocean. The light in these (e.g., *Thaumantias*) gleams round the margin and along the four radii.

The Ascraspedote Medusæ have also been signalised as factors in producing the phosphorescence of the sea, such forms as *Pelagia noctiluca* and *Pelagia cyanella* being especially prominent. Spallanzani, indeed, made an elaborate series of experiments on the luminosity of the Medusæ in his voyage to the Two Sicilies. Some of these, as *Dactylometra* (*Pelagia*) *quinquecirra,* Agassiz, are nocturnal in their habits. They are only occasionally found floating at the surface during the day, while at night, in the same localities, the bottom swarms with these large masses of dull phosphorescence, moving about with the greatest rapidity.[7] Species of *Rhizostoma* were likewise observed by Giglioli to have a pale bluish luminosity. The two most abundant Medusæ of our eastern shores, viz., *Aurelia aurita* and *Cyanea capillata* (both in its young purple and adult brown condition), so far as I can make out, exhibit no luminosity. This agrees with the views expressed long ago by Ehrenberg.

The oceanic Hydrozoa (*Siphonophora*) are likewise characterised by their

[5] Even after many days and in impure water some of these retain this property, a shock to the stem sending off a crowd of luminous points from the trophosome.

[6] *Zoological Researches*, vol. i. part i. mem. iii. p. 48. 1829.

[7] Agassiz, *North American Acalephæ*, p. 49. Cambridge, 1865.

phosphorescence. Thus Giglioli met with luminosity in *Abyla, Diphyes, Eudoxia, Praya* and *Aglaismoides*. Dr. Bennett [1] has also observed luminosity amongst the Coralligenous Actinozoa; the grazing of a boat on a coral reef causing a vivid stream of phosphoric light. Similar observations were made on Madrepores by Giglioli,[2] the light in this case being bright greenish and enduring some minutes.

Amongst the Alcyonarians the luminosity of the common Sea-Pen (*Pennatula phosphorea*) has been long known, and was studied by Gesner, Bartholin, Adler, and others. In the earlier part of this century Grant gave the oft-quoted description,[3] in which he pictures a *Pennatula* 'with all its delicate transparent polypi expanded and emitting their usual brilliant phosphorescent light, sailing through the still and dark abysses by the regular and synchronous pulsations of the minute fringed arms of the whole polypi.' But it ought to be balanced by his concluding statement, that the sea-pens are probably stationary, or 'lie at the bottom, and move languidly like Spatangi, Asteriæ or Actiniæ.' [4] Edward Forbes again observed that the light proceeded from the irritated point to the extremity of the polypiferous portion, and never in the opposite direction. As Dr. George Johnston tells us, Forbes induced Dr. George Wilson to test, along with Professor Swan, the polyps during phosphorescence by a delicate galvanometer, but without result. He thought the luminosity was due to a spontaneously inflammable substance.

More recently a series of interesting observations were made by Panceri on the structure and physiology of the luminous organs of this form. His conclusions are (1) that the light emanates from the polyps and zoids; (2) that the phosphorescent organs are the eight white cords adhering to the outer surface of the stomach, and that these are chiefly composed of cells containing a substance of a fatty nature, the oxidation of which causes the light. Panceri's conclusions further considerably modify Forbes's views about the direction of the waves or points of light. He supposes that the elements which stand in the place of nerves are capable of producing in the luminous batteries of the polyps a momentary oxidation—more rapid and more intense—accompanied by phosphorescence. Like those examined by Professor Milnes Marshall,[5] the specimens at St. Andrews, after irritation, show a series of brilliant coruscations which flash along the rows of polyps in a somewhat irregular manner.

Two other Alcyonarians, *Funiculina* and *Umbellularia*, are equally phosphorescent. Though the former is familiar enough to some of the long liners of the outer Hebrides and west coast, it is rare that either is procured for scientific investigation. *Funiculina quadrangularis*, according to Forbes,[6] gives out a vivid bluish light, which comes from the bases of the polyps, and appears to be connected with the reproductive system. Sir Wyville Thomson [7] describes the specimens procured in the 'Porcupine' as resplendent with a steady pale lilac phosphorescence like the flame of cyanogen; and always sufficiently bright to make every portion of a stem caught in the tangles distinctly visible. The same zoologist mentions that the stem and polyps of *Umbellularia* are so brightly phosphorescent, that Captain Maclear found it easy to determine the character of the light by the spectroscope. It gave a restricted spectrum sharply included between the lines *b* and D.[8]

Besides the foregoing Alcyonarians, *Isis* and *Gorgonia* have been indicated as likewise phosphorescent. Dr. Merle Norman and Dr. Gwyn Jeffreys (whose death since the last meeting of the British Association is a serious loss to science) mention a beautifully luminous *Isis* on board the French ship 'Le Travailleur'; and Sir Wyville Thomson,[9] with the facile and genial pen which characterised the

lamented naturalist, gives a fascinating picture of a long, delicate, simple Gorgonian which came up in immense numbers in the trawl from 600 fathoms off the Spanish coast. He conjures up this Gorgonian forest as an animated cornfield waving gently in the slow tidal current, and glowing with a soft diffused phosphorescence, scintillating and sparkling on the slightest touch, and now and again breaking into long avenues of vivid light, indicating the paths of fishes or other wandering denizens of these enchanted regions. Professor Moseley thinks that this brilliant phosphorescence of the Alcyonarians may be regarded as an accidental production, but that it may be of occasional service. Further, that the deep sea is at any rate lighted up by these Alcyonarians, which would thus form luminous oases round which animals with eyes might possibly congregate.[1]

The last group of the Cœlenterates, the *Ctenophora*, are even more conspicuous than the foregoing in regard to luminosity. It is indeed long since the Abbé Dicquemare descanted on *Cydippe* (*Pleurobrachia*) and Suriray on *Beroë*, while subsequent authors have made it clear that the majority of this group are phosphorescent. In our own seas, as Professor Allman observes, *Beroë* at various stages is one of the most prominent luminous forms during certain seasons. Their enormous numbers make their effects more striking, though the intensity of the phosphorescence is less than that of the Medusæ. Quiet seas like Bressay Sound and the Firth of Forth are occasionally covered by a dense layer of these animals. Professor Allman found that *Beroë* did not phosphoresce if suddenly taken from light into darkness, but that after they had remained about twenty minutes in obscurity they became luminous. Considerable variety exists in this respect at St. Andrews, some emitting light at once, others showing none. It is probable that this uncertainty is connected with the hygienic condition of the individuals.

In foreign seas many brightly luminous species are met with. Thus Professor A. Agassiz[2] describes *Mnemiopsis Leidyi* as 'exceedingly phosphorescent, and when passing through shoals of these Medusæ, varying in size from a pin's head to several inches in length, the whole water becomes so brilliantly luminous that an oar dipped up to the handle can plainly be seen on dark nights by the light so produced; the seat of the phosphorescence is confined to the locomotive rows, and so exceedingly sensitive are they that the slightest shock is sufficient to make them plainly visible by the light emitted from the eight phosphorescent ambulacra.' The same author[3] mentions that *Lesueuria* has a very peculiar bluish light of an exceedingly pale steel colour, but very intense. Giglioli, again, found that the beautiful riband-like *Cestus* shone with a reddish yellow light, but in *Eucharis* the latter was intensely blue.[4]

While many of the preceding group are pelagic at all periods of their existence, the luminous star-fishes are in their adult condition members of the bottom fauna. The larval stages of the brittle-stars, however, are passed at the surface of the water, where it is probable they add their quota to swell the ranks of the phosphorescent types. Amongst the first to note this property in the brittle-stars was Professor Viviani, who found on the shores of Genoa a little brittle-star which he termed *Asterias noctiluca*,[5] and which probably is identical with the *Amphiura elegans* of Leach. Péron likewise mentions the phosphorescence of his *Ophiura phosphorea*. Sir Wyville Thomson observed in the 'Porcupine' that the light from *Ophiacantha spinulosa* was of a brilliant green, coruscating from the centre of the disk along the rays and illuminating the whole outline of the starfish.[6] More recently, Professor Panceri of Naples has re-examined the phosphorescence of the species described by Viviani, and he finds that though with the first momentary glow the whole ray is lit up with a greenish light, the luminous points corre-

[6] *Depths of the Sea*, p. 98.

spond with the bases of the pedicels and are ranged in pairs along the arms.[1] In deep water (between 20 and 40 fathoms) off our eastern shores, *Ophiothrix* gleams all over the trawl-net with a pale greenish light; but the adults of same form between tide marks give no trace of luminosity.

The older authors were familiar with certain luminous annelids which they termed *Nereides,* such as *Nereis phosphorans.* Ehrenberg paid considerable attention to this group, specially referring to *Polynoë fulgurans* from the North Sea, *Nereis noctiluca*[2] and *Nereis* (*Photocharis*) *cirrigera,* the latter species having a photogenic structure in its cirri like the electric organ of the Torpedo. This form is probably related to the ubiquitous *Eusyllis,* which, under various names, has been noticed by many observers. Thus very likely it is the same species that is mentioned by Harmer, in Baker's 'Employment for the Microscope,'[3] as having been found on oyster shells; and also by Vianelli, who describes it as a caterpillar-like form amongst seaweeds. Indeed the Syllideans have been conspicuous in the literature of phosphorescence from the time of De la Voie,[4] and Vianelli,[5] to the recent period of Claparède[6] and Panceri.[7] The structure of the cirri of the phosphorescent forms, however, gives no support to the opinion of Ehrenberg that they possess a special photogenic structure.

The luminous annelids group themselves under five families, viz., the Polynoidæ, Syllidæ, Chætopteridæ, Terebellidæ, and Tomopteridæ, and the number may yet be extended to include other pelagic types.

In the first family one of the most abundant is *Harmothoë imbricata,* which lives both between tide-marks and in deep water, and is cosmopolitan in geographical distribution. It discharges bright greenish scintillations from the point of attachment of each dorsal scale; and thus, under irritation, the flashes are arranged in pairs along the body, or in a double moniliform line. If severely pinched the worm wriggles through the water, emitting sparks of green light from the bases of the feet. The separated scales also continue to gleam for some time, chiefly at the surfaces of attachment (scars), near which, in each, a ganglion exists. The same phenomenon is readily produced in a fragment either of the anterior or posterior end of the body. No mucous secretion is emitted, but the light is clearly produced by the will of the animal, and by the agency of its nervous system. A recent writer, Dr. Jourdan,[8] has endeavoured to prove that this luminosity in another member of the Polynoidæ (viz., *Polynoë torquata*) is produced by cells secreting a phosphorescent mucus, but this view is by no means applicable in all cases.

Besides the species mentioned, various other forms in this family are equally luminous, such as *Polynoë scolopendrina, Achloë astericola, Polynoë lunulata,* and a Zetlandic *Eunoa.*

As an example of the Syllidæ, the common *Eusyllis,* so often mentioned by previous authors, may be taken. Under irritation a fine green light is emitted from the ventral aspect of each foot, and the scintillations seem to issue from many points at each space, flash along both sides of the worm posterior to the point of stimulation, and then disappear. Under severe irritation the animal remains luminous behind the injured part for nearly half a minute, while the surface of granular light on each segment is larger than usual, and in some instances those of opposite sides are connected on the ventral aspect by a few phosphorescent points. The body behind the irritated region has a paler pinkish hue immediately after the emission of light, showing that the luminosity is diffused.

In the Chætopteridæ the phosphorescence is remarkably beautiful, bright flashes being emitted from the posterior feet; but the most vivid luminosity is at a point on the dorsum between the lateral wings of the tenth segment. Here the abundant

mucus exuded by the animal can be drawn out as bluish-purple fire of great intensity, which, besides, now and then gleams along the edges of the wing-like processes, and illuminates the surrounding water. A very characteristic odour, somewhat resembling that produced by phosphorus in combustion, is given out by the animal during such experiments. In this connection it may be observed that Quoy and Gaimard mention that an odour similar to that around an electric machine is given out by luminous marine annelids.

Amongst the Terebellidæ, as first shown by Grube, none excel the genus *Polycirrus* in the brightness of the phosphorescence and the ease with which it is elicited. Mere blowing on the water of the dissecting-trough suffices to cause in the British *Polycirrus* the most vivid pale bluish luminosity, which gleams for a moment along every one of the remarkably mobile tentacles. Long before Grube, however, had discovered the phosphorescence of *Polycirrus*, our patient and laborious countryman, Sir J. Graham Dalyell,[1] had noticed it in the group, for he mentions that when irritated *Terebella figulus* gives out the most copious blue refulgence, intermingled with a reddish flame. Another member of this family, viz., *Thelepus*, is only faintly phosphorescent in life, but when decomposition has made progress it gleams in the vessel with a pale lambent light, somewhat like phosphorus in air.

In the pelagic Tomopteridæ certain peculiar structures on the parapodia, formerly supposed by some to be eyes, and by others simply glandular organs, were lately found by Professor Greeff[2] to be luminous organs, which, though glandular, have a considerable nervous supply, including a ganglion.

Panceri's observations on the luminous annelids of Naples and the peculiar type *Balanoglossus* (Enteropneusta) have recently added considerably to our knowledge of the subject. He specially describes, in *Chætopterus*, the structure of the phosphorescent glands in the great pinnules and other parts, which produce the luminous mucus. With some reason, he concludes that two kinds of phosphorescence are present in annelids, viz., one which is the result of purely nervous action, and another which is due to this *plus* a luminous secretion.

A Turbellarian, viz., *Planaria retusa*, was mentioned by Viviani[3] as luminous, but this feature appears to be rare in the group; and the same may be observed of phosphorescent Rotifers, one of which (*Synchæta baltica*) was described by Ehrenberg.[4] Giglioli,[5] again, records a *Sagitta* which showed a feeble luminosity in the posterior region of the body.

The minute forms amongst the Crustacea (chiefly Copepoda) were recognised as phosphorescent by Athanasius Kircher in 1640, and have been mentioned by most authors who have alluded to the subject since that date.[6] Thus Viviani gives seven species from the shores of Genoa, and Tilesius no less than nineteen luminous crustaceans from Krusenstern's voyage. Dr. Baird describes the light given out by those met with in his cruises as brilliant in the extreme, and Vaughan Thompson added considerably to our knowledge of *Sapphirina* and of the luminous schizopods, an example of which had been discovered by Sir Joseph Banks, and described by Macartney.[7] Most authors agree that the minute forms, such as the Copepods, give a sparkling appearance to the surface of the water. The light in these, according to Lesson, proceeds from glands placed on the sides of the thorax; while Giglioli found the luminous organ of the cosmopolitan *Sapphirina* in the anterior part of the thorax. On the other hand, Captain Chimmo[8] thought it was decomposing food in the stomach, and Professor Moseley[9] in certain cases entertained a similar opinion. The phosphorescence of the Euphausiidæ was a prominent feature in the voyage of the 'Challenger,' brilliant flashes being emitted on capture from a series of spots along the trunk and tail. Mr. Murray also met with a diffused light in the Faröe channel when dredging in the 'Triton,' and he attributed this to the

phosphorescent organs of *Nyctiphanes norvegica*, M. Sars, one of the same group. Professor G. O. Sars describes these organs as composed of a series of coloured globules, the lens-like body of which acts as a condenser, and thus enables the animal to produce at will a bright flash of light in a given direction.[1]

Marine phosphorescence has some of its most striking examples amongst the Tunicates. One of the best known instances is that of *Pyrosoma*, the light from which has been so graphically described by M. Péron, Professor Huxley, and other naturalists who have had an opportunity of observing it. It proceeds in each member of the compound organism from two small patches of cells at the base of each inhalent tube. These cells contain a substance resembling fat. *Salpa* has frequently been mentioned as a luminous form by many authors, but Delle Chiaje found that in the Mediterranean *Salpa pinnata* was not phosphorescent; and amongst the multitudes of Salpæ which for some weeks abounded at Lochmaddy in North Uist, neither the former nor the *Salpa spinosa* of Otto exhibited this property, though a spark was occasionally seen in the nucleus in some specimens, probably from the food. Giglioli likewise is doubtful concerning them, but in one instance a brilliant rose-coloured light appeared in the nucleus. *Doliolum*,[2] on the other hand, shone with a greenish tint, while examples of *Appendicularia* which he encountered in various seas were chameleon-like in their luminosity, and often gleamed with great brightness.

Various mollusks exhibit the property of phosphorescence. Fabricius ab Aquapendente mentions *Sepia*, Panceri *Eledone*, Adler *Chama* and '*Dactylus*.' The best known is *Pholas dactylus*, which possesses two wavy bands and triangular organs of ciliated epithelium on the inner surface of the mantle. These secrete a luminous substance, soluble in ether and alcohol, which illumines the excurrent water. The light is also maintained for a long time during putrefaction, as in the case of *Thelepus*. Panceri found that carbonic acid extinguished the light, but that air re-illuminated it, just as Johannes Müller had previously observed in a vacuum and in air. The light is monochromatic, the bands having a constant place in connection with the solar spectrum (from line E to line F).

Several Pteropods likewise contribute to the phosphorescence of the sea. Thus Giglioli noticed that a *Cleodora* gave out a vivid reddish light, while a *Criseis* and a *Hyalæa* were luminous at the base of the shell. He mentions also a large unknown Heteropod[3] in the Indian Ocean, which glowed with a reddish phosphorescence. Amongst the Dermatobranchs, *Phyllirrhoë* has the same property. Giglioli further found that *Loligo sagittatus* and a small *Octopus* gleamed all over with a whitish luminosity.

Phosphorescence in living fishes appears to have been accurately observed within a comparatively recent date, though the luminosity of dead fishes has been known from very early times, and has been the subject of many interesting experiments such as those of Robert Boyle on dead whitings,[4] and Dr. Hulme on herrings.[5] I do not mean to say that the literature of the so-called phosphorescent fishes is scanty, for it extends from the days of Aristotle and Pliny to modern times, but that the writers have had little reliable evidence in regard to living fishes to bring forward. Thus of upwards of fifty fishes entered by Ehrenberg in his list it is hard to say that one is really luminous during life. In many cases it is probable that the supposed phosphorescence of large forms, such as sword-fishes and sharks, has arisen from the presence of multitudes of minute phosphorescent animals in the water, just as the herring causes a gleam when it darts from the side of a ship. Professor Moseley, for instance, observed in the 'Challenger' that when large fishes, porpoises, and penguins dashed through phosphorescent water, it was brilliantly lit up, and their track marked by a trail of light. The same feature is observed in hooked fishes, and it is known that fishermen are doubtful of

success when the sea is very phosphorescent, for the presence of the net in the water excites the luminosity and scares the herring. Little is known with regard to the luminosity of the 'Pearl-sides'[1] of our own shores, though from its wide distribution this lack of information seems to be remediable.

One of the most striking instances of phosphorescence in living fishes is that of the luminous shark (*Squalus fulgens*) found by Dr. Bennett. This is a small dark-coloured shark, which was captured on two or three occasions at the surface of the sea. It emitted without irritation a vivid greenish luminosity as it swam about at night and it shone for some hours after death. The phosphorescence appears to be due to a peculiar secretion of the skin. The eyes of the shark were more prominent than usual in such forms.[2]

In recent times phosphorescence has generally been associated with deep-sea fishes. Thus in a narrative of the early part of the voyage of the 'Challenger'[3] Sir Wyville Thomson mentions ranges of spots or glands producing a phosphorescent secretion on the body of a fish pertaining to the Sternoptychidæ a species of which (*Argyropelecus hemigymnus Cocco*) is included by Mr. Francis Day in his history of British fishes. In a new *Echiostoma* (one of the Stomiatidæ) also the two rows of probably phosphorescent dots along the body were red, surrounded by a circle of pale violet.[4] Dr. Günther[5] observes that many deep-sea fishes have round, shining, mother-of-pearl bodies embedded in the skin. These are supposed to be producers of light, and they have been observed to be phosphorescent in two species of Sternoptychidæ. He further states that the whole muciferous system is dilated in deep-sea fishes, that is, fishes inhabiting 1,000 fathoms or more, and that the entire body seems to be covered with a layer of mucus, the physiological use of which is unknown; it has been noticed to have phosphorescent properties in perfectly fresh specimens.

Having thus briefly reviewed the leading features of phosphorescence in marine animals, a glance may now be taken at the supposed causes and purposes of this provision.

I do not deem it necessary to go into detail with regard to the numerous views which have been advanced to account for the phosphorescence of marine organisms, for these range over a very wide area—from its production by electricity, the constant agitation of the water, by putrefaction, by luminous imbibition, to its manifestation as a vital action in the animals, or a secretion of a phosphorescent substance. Ehrenberg considered it a vital act similar to the development of electricity, and sometimes accompanied by the secretion of a mucilaginous humour which is diffused around; while others, such as Meyen, thought it only a superficial oxidation of the mucous coat, or a luminous secretion from certain glands. Some believed that a liquid containing phosphorus was secreted, and that this underwent slow combustion; while others explained that it was a nervous fluid modified by certain organs to appear as light. Coldstream thought it was due to an imponderable agent, and that phosphorus or an analogous substance might enter into the organs producing it. De Quatrefages, again, affirms that it is produced in two ways: (1) by the secretion of a peculiar substance exuding from the entire body or a special organ; and (2) by a vital action independent of all material secretion. Panceri was strongly impressed with the importance of fatty matter in the forms he examined—such as *Pennatula*, the Medusæ, Beroïdes, Pholades, *Chætopteri* and *Noctilucæ*—the phosphorescence arising from the slow oxidation of this substance; the nervous system of the living animal, however, being capable of producing a momentary oxidation more rapid and more intense, accompanied by light.

It will be observed that in the Protozoa the structure of the minute but often very abundant animals which furnish the luminosity clearly proves that

[1] *Maurolicus pennantii*, Cuv. and Val.

[2] The Danish naturalist Reinwardt describes a phosphorescent fish (*Hemiramphus lucens*) from the Moluccas. *Fide* Giglioli, *op. cit.* p. 503.

[3] *Nature*, August 28, 1873.

[4] '*Challenger*' *Narrative*, Zoology, I. part ii. p. 521.

[5] *Ibid.* I. vol. ii. p. 905.

the presence of a well-defined nervous system is not required for its manifestation, the protoplasm of their bodies alone sufficing for its development. There are no glands for secreting it, and in some apparently no fatty matter for slow combustion. In the Cœlenterates the phenomena appear to be more nearly related to nervous manifestations, though in certain cases the luminous matter possesses inherent properties of its own. While in some annelids, such as *Chætopterus* and *Polyirrus*, there are glands which may be charged with the secretion of a luminous substance, it is otherwise with certain Polynoidæ, in which the emission of light appears to be an inherent property of the nervous system. The irritability in the phosphorescent examples of the latter family, however, varies considerably, some, *e.g.*, *Polynoë scolopendrina*, being sluggish, while others, like *Harmothoë*, are extremely irritable. In the Crustaceans the luminosity seems to have the nature of a secretion, probably under the control of the nervous system. In *Pyrosoma* and *Pholas dactylus* a luminous secretion is also a prominent feature, and in both the latter and the annelids decay excites its appearance, as also is the case, to a limited extent, in fishes.

It is evident, therefore, that the causation of phosphorescence is complex. In the one group of animals it is due to the production of a substance which can be left behind as a luminous trail. The ease, for instance, with which in *Pennatula* and other Cœlenterates the phosphorescence can be repeatedly produced by friction on a surface having a minute trace of the material, clearly points to other causes than nervous agency. On the other hand again, as in certain annelids, it is purely a nervous action, probably resembling that which gives rise to heat. The action, moreover, evidently affects the organic chemical affinities of the tissues engaged.

With the exception of such as Macartney, the older authors, who in some cases took an imaginative view of the question, connected the emission of light with the special economy of the deep sea. The speculations to this effect are fairly summarised in 'Brewster's Edinburgh Encyclopædia,' published in 1830.[1] Thus it is supposed that total darkness exists at the depth of 1,000 feet, and that the phosphorescence of marine animals is a substitute for the light of the sun. Moreover, that by these lights the animals on the one hand are guided for attack, and on the other their power of extinguishing them enables them to escape destruction. Fishes are known to prey chiefly at night, and the writer supposes that the phosphorescence of their prey guides them; for, he says, this luminosity is particularly brilliant in those inferior animals which from their astonishing powers of reproduction, and from a state of feeling little superior to that of vegetables, appear to have been in a great measure created for the food of the more perfect kinds. Dr. Coldstream at a later period (1847) reproduced the same views in his article on animal luminosity.[2]

The same notion was brought forward in the 'Report of the Cruise of the "Porcupine."'[3] and special reference was made to the young of certain starfishes, which are stated to be more luminous than the adults, that being part of the general plan which provides an excess of the young of many species, apparently as a supply of food, their wholesale destruction being necessary for the due restriction of the multiplication of the species, while the parent individuals, on the other hand, are provided with special appliances for escape or defence. Thus phosphorescence, it is further asserted,[4] in very young Ophiacanthæ just rid of their plutei, in a sea swarming with predaceous crustaceans, such as *Dorynchus* and *Munida*, with great bright eyes, must be a fatal gift. Some naturalists still appear to hold a similar, though perhaps modified, view. Much caution, however, is necessary in theorising on this head.

In the first place, phosphorescent animals do not appear to be more abundant in the depths of the sea than between tide-marks or on the surface, the latter perhaps presenting the maximum development of those exhibiting this phenomenon.

[1] Chiefly the views of Dr. Macculloch.
[2] Todd's *Cyclop. of Anat. and Phys.*
[3] *Proc. Roy. Soc.* No. 121, 1870, p. 432.
[4] *Depths of the Sea*, p. 149.

Very many of the young that have been indicated as so brilliantly luminous become surface-forms soon after leaving the egg, and thus at their several stages more or less affect the three regions—of surface, mid-water, and bottom.

A survey of the life-histories of the several phosphorescent groups affords at present no reliable data for the foundation of a theory as to the functions of luminosity, especially in relation to food. No phosphorescent form is more generally devoured by fishes or other animals than that which is not; and, on the other hand, the possessor of luminosity, if otherwise palatable, does not seem to escape capture. An examination of the stomachs of fishes makes this clear, except perhaps in the case of the herring, which, however, is chiefly a surface-fish. Further, it is not evident that such animals are luminous at all times, for it is only under stimulation that many exhibit the phenomenon.

Moreover, the irregularity of its occurrence in animals possessing the same structure and habits in every respect, strengthens the view just expressed. Thus, while *Pholas dactylus* has been known from the days of Pliny to be luminous, the common *Pholas crispata* is not so endowed. Two annelids (*Harmothoë imbricata* and *Polynoë floccosa*), abound between tide-marks and closely resemble each other in habits and appearance; yet one is brightly luminous, while the other shows no trace. Instead of luring animals for prey, or affording facilities for being easily preyed upon, the possessors of phosphorescence in the annelids are often the inhabitants of tubes, or are commensalistic on starfishes. Indeed, every variety of condition accompanies the presence of phosphorescence in the several groups, so that the greatest care is necessary in making deductions, especially if these are to have a wide application.

In the foregoing brief outline of the remarkable phenomenon of phosphorescence as it affects marine animals, it is apparent that, though a considerable increase in our knowledge has taken place during the last quarter of a century, much more yet remains to be done. I, however, confidently look forward for further advances, in this as well as in other departments, to the marine laboratories of the country—I mean such institutions as those now in working order at Granton, St. Andrews and Tarbert, as well as the larger establishment proposed to be erected by the Biological Association at Plymouth. These laboratories, it is true, have been tardily instituted, but it is satisfactory to think that at last the zeal and methods of the workers have, and will have, a better field for their exercise than formerly, and that the zoology of the fisheries will obtain that attention which its importance to the country necessitates.

The following Papers and Reports were read:—

1. *On the Tay Whale* (Megaptera longimana) *and other Whales recently obtained in the district. By* Professor STRUTHERS, *M.D., LL.D.*

1. *Megaptera longimana.* Male, 40 feet long. January 1884. Wounded near Dundee. Brought ashore dead at Stonehaven, near Aberdeen. Presented the usual external characters of this species. Pectoral fin 12 feet long, but finger muscles only about half as well developed as in *B. musculus.* Femur entirely cartilaginous, conical form, right 5½ inches, left 4 inches in length. The skeleton was exhibited to the Section, and its chief characters commented on.

2. *Balænoptera musculus.* Male, 50 feet long. Stranded at Nairn, December 1884; exhibited and dissected at Aberdeen. Presented the usual external characters of *B. musculus.* Finger muscles, the same arrangement as described by the author in *B. musculus,* at the 1871 meeting of the Association. Femur cartilaginous, oval form, about an inch in length. The skeleton was exhibited to the Section.

3. *Balænoptera borealis.* Male, 36 feet long. Killed at Widewall Bay, Orkney, December 1884. Whalebone fringe presented soft character since noticed by Guldberg. Femur absent. Finger-muscles nearly the same as in *B. musculus.* Skeleton exhibited to the Section, and the osteological characters which further distinguish it from *B. musculus* commented on, especially stylo-hyal, nasal, cervical

vertebræ, and orbital plate of frontal bone. Ribs, fourteen pairs, the first pair double-headed.

4. *Beluga.* Killed at Wick, 1884. Skeleton and photograph showing natural form, exhibited to the Section.

---

2. *Is the Commissural Theory of the Corpus Callosum correct?* *By* Professor D. J. Hamilton, *M.B.*

The results recorded by the author were obtained by certain special methods of preparation. They went to prove that the corpus callosum is not an interhemispherical commissure, as is generally supposed, but that it is in reality the decussation of a particular system of fibres on their way downwards to join the inner and outer capsules. These fibres are not to be confounded with the motor and other direct fibres derived from the cerebral cortex which decussate at some point lower down.

The facts bearing upon the above were briefly as follows:—(1) The fibres can be seen with the naked eye turning down to join the two capsules, after issuing at each side from the tectorial part of the corpus callosum.

(2) They can be traced with the microscope from the corpus callosum continuously down to the two capsules.

(3) The mass of fibres thus turning downwards forms an arch, varying in shape in different localities, but corresponding in extent to the position of the corpus callosum. This arched system of fibres ('the crossed callosal tract') can be exposed by dissecting off the superjacent cortex and medullary substance. Their curved course can then be distinctly seen with the naked eye.

(4) In young embryos of mammals, and more especially in the human embryo of from three to four months, the callosal system of fibres is much more developed than any other, and hence it appears to be more differentiated than in the adult, where it is obscured by the other systems of fibres around it. The course of the fibres in the embryo is exactly similar to that described in the adult. After leaving the corpus callosum they curve downwards in a ribbon-like band to join the two capsules.

(5) The brain of a woman fifty-three years of age was shown, in which the right first and second frontal convolutions had been destroyed probably in infancy. Corresponding with this the tectorial part of the corpus callosum was extremely small, and the *opposite* inner and outer capsules were almost wanting, while those on the *same* side were comparatively well developed. The basal ganglia on the *opposite* side were also extremely small.

(6) The ultimate destinations of those callosal fibres entering the inner capsule are probably the caudate nucleus, the thalamus opticus, the grey matter of the pons, the cerebellum (?), the ganglionic masses in the medulla oblongata, and possibly the spinal cord. Of those entering the outer capsule the following points of attachment had been made out:—the olfactory tract, the optic tract, the inner capsule (a few fibres), and the temporo-sphenoidal lobe.

(7) The callosal fibres derived from the frontal and occipital regions follow essentially the same course as those arising from the vertex.

---

3. *The Evidence of Comparative Anatomy with regard to Localisation of Function in the Cortex of the Brain.* *By* Alex. Hill, *M.A., M.B., M.R.C.S.*

The central nervous system is formed as an involuted tube of epiblast, from the cells composing which the nerve fibres grow out. Throughout the greater part of the system the cells form the inner, the fibres the outer portion of the tube's wall. In its anterior part, where the tube is dilated into the cerebral vesicles, a layer of cells is also disposed outside the white fibre tube. Throughout the central grey tube the cells are arranged in groups, from which spring the nerve fibres for each metamer, the cells in each group being distinguishable into those which are con-

nected with sensory, those which are connected with motor, and those which are connected with visceral fibres. The central grey tube includes the optic thalamus, and the key to its constitution is to be found in its segmentation.

The object of this investigation is to determine the relation borne by the several parts of the peripheral grey tube (the cortex mantle) to the segments of the central grey tube, and indirectly, therefore, to the several body nerves. It may be that the processes of the cells of the central grey tube, the commissural nerves, as they may be called, are woven, as it were, when they reach the cortex into a colourless web, or, on the other hand, they may retain and impart to separate regions of the cortex the tone which they have received from sense organ and motor mechanism. The latter of these suppositions is supported by experimental research, for stimulation of particular regions of the cortex indicates the occupation of those regions by the cerebral centres of particular nerves. On such evidence is based the theory of 'localisation of function.' Eventually, however, this theory must be submitted to a comparative test. Animals differ from one another widely in their sensory and motor endowments. Such differences are clearly indicated by the varying cross-sections of their several nerves, and if particular regions of the cortex are in functional relation with particular nerves, the extent of their development will vary with the size of the nerves. To the superficial regional development of the cortex the fissures are the only possible guides. It is, therefore, of the highest importance to determine their homological value; that they may be safely accepted as boundary-lines is shown by the constancy of their arrangement in animals of any one type, the uniformity of their development and progressive extension, and the fact that the first to appear are the most constant in the animal series and the deepest in the individual. To reduce the matter to statistics, the superficial areas of regions bounded by certain fissures should be compared with the cross-sections of their correlated nerves. As yet no system of mensuration has been devised for the cortex. In the more divergent animals, however, the proportional development of the various regions of the cerebrum is obvious to the eye.

In herbivora, which depend for safety upon sight and upon repeated simple movements of the limbs, the internal part of the occipital lobe, as shown by the deflection of the lateral fissure, is large, the sigmoid gyrus small. In carnivora, which depend for their food upon the sense of smell and the complexity of their muscular system, the temporo-sphenoidal lobe and the sigmoid gyrus are both conspicuous for their development. That these great differences do not depend upon the distance apart of the animals phylogenetically is shown by the fact that in the pig, which seeks its food with its nose, the brain approaches the carnivorous rather than the herbivorous type. Amongst carnivora the otter is conspicuous for the small development of its olfactory apparatus; the temporo-sphenoidal lobe is correspondingly small. In this animal the fifth nerve is very large, which accounts apparently for the large size of the convolution which lies in front of the fissure of Sylvius. Cats are remarkable for the uniform development of their senses. With this uniformity is associated a remarkable symmetry of brain. Hearing, however, is in these animals particularly acute; the cortical localisation of this sense appears to be above the processus acuminis of the fissure of Sylvius. In the main these results are confirmatory of those obtained by Ferrier and other experimental physiologists. The order in which the centres are situate on the cortex indicates that the cerebrum has undergone a rotation backwards into a single turn of a spiral coil.

FRIDAY, SEPTEMBER 11.

The following Papers were read:—

1. *Recent Observations on the Habits and Instincts of Ants and Bees. By* Sir JOHN LUBBOCK, *Bart., F.R.S.*

2. *On the Carpal Bones in various Cetaceans. By* Professor STRUTHERS, *M.D., LL.D.*

Dissections exhibited of the carpal bones and cartilages in *Hyperoodon, Beluga, Globicephalus, Narwhal, Balænoptera musculus, B. borealis, B. rostrata, Megaptera longimana*, and *Balæna mysticetus.* The various carpal cartilages, more or less ossified, shown to be mapped out by fibrous and occasionally by partially synovial articulations. The general conclusion of the author is, a diminution in the number of the second carpal row from *Hyperoodon* to *Mysticetus.* In *Mysticetus*, second row reduced to one cartilage or bone, partially ossified in a 35 feet-long male, entirely cartilaginous in a full-grown female. Sections display these facts fully. The pisiform varies in its development. In some it appears as if partially continuous with the cartilaginous epiphysis of the ulna. In *B. borealis* the trapezoid is wanting, in contrast with *B. musculus.*

3. *Account of the Dissection of the Rudimentary Hind-limb of* Balænoptera musculus. *By* Professor STRUTHERS, *M.D., LL.D.*

A careful dissection was made of the anatomical relations of the femur, &c., in the whale from Nairn, and full-sized drawings were made as the dissection proceeded. The femur is imbedded in fibrous tissue, belonging to transverse and longitudinal aponeuroses. Only a small part of a superficial muscle is attached to it. It is loosely held to the pelvic bone by ligaments. No synovial membrane, but an acetabular cartilage is present, concealed by the periosteum. The terminal fibrous band from the femur expands in fascia some inches forwards. The author's conclusion is, that the femur in *B. musculus* is to be regarded as entirely a rudimentary structure. The paper embraced an account of the formation of the pelvic cavity, and of the muscles and fibrous structures connected with the pelvic bones.

4. *Some points in the Anatomy of Sowerby's Whale* (Mesoplodon bidens).[1] *By* Professor W. Turner, *M.B., F.R.S.*

5. *On the use of Graphic Representations of Life-histories in the teaching of Botany.* *By* Professor F. O. Bower.

The object of this paper was to bring before the notice of teachers of botany such diagrammatic representations of life-histories of plants as had previously been published by the author in the Journal of the Linnæan Society, in a paper 'On Apospory in Ferns,' and with this object the author had prepared a series of figures, of which those relating to the ferns were similar in their main points to those published in the paper above referred to: the series was, however, further extended to the higher forms. It was clearly laid down that in the opinion of the author, and according to his constant practice, these figures are only to be used *after* the chief characters of the plants in question, and their processes of development and reproduction, have been described in detail by the teacher: in fact, that they are intended to serve *only* as a simple recapitulation of the main facts, from which comparative conclusions may be the more easily drawn by the teacher, and presented forcibly to the mind of the student. If used in any other way, there is great danger of the graphic method being a stumbling-block and hindrance to true progress. After describing the proposed diagrams in detail, and giving incidentally a description of the newly-discovered and interesting phenomenon of apospory in ferns, the author proposed the following questions for discussion by the teachers present:

1. Are such diagrams as these to be used at all?
2. Is it judicious to load them with further details?
3. How far may their use be extended to the lower forms?

Supplementary Meeting.—PHYSIOLOGY.

1. *On the Direct Action of Anæsthetics on the Frog-heart.* *By* J. McGregor-Robertson, *M.A., M.B.*

This was an investigation into the action of anæsthetics on the excised heart of the frog. The heart was bound to the Kronecker canule, and connected with the frog-heart apparatus of Ludwig. The recording point of the mercury manometer traced the characters of the contractions on the recording surface of the cylinder of a kymographion.

At intervals nourishing fluid (consisting of defibrinated rabbit's blood, one part, and ·6 per cent. salt solution, two parts) was passed through the heart, the arrangement of the apparatus permitting the nourishing fluid containing a percentage of the drug experimented with being supplied to the heart instead. The anæsthetics used were found to vary in their action according to the dose. A small percentage stimulating the heart, and increasing the rapidity of the movement, a greater percentage lessening both the force and frequency, and a third completely paralysing the heart, and stopping all movement, so that even mechanical stimulation failed to arouse the heart. In all cases, however, a few cubic centimetres of normal fluid restored the heart to its former vigour. The recovering heart passed backwards through the various stages of the action of increasing doses of the anæsthetics.

It was shown with ether that a dose sufficient to stimulate at a low temperature caused complete standstill at a higher temperature (35° C.), and that a dose which

[1] Published *in extenso* in the *Journal of Anatomy and Physiology*, October, 1885.

caused standstill at the ordinary temperature failed to do so at a reduced temperature (5° C.). A heart reduced to standstill by a 1° per cent. solution of ether at a temperature of 35° C. recommenced beating on lowering the temperature.[1]

A marked quantitative difference was shown between the different anæsthetics, as shown in the following table, where the percentage of the drug required to stimulate, to reduce, or to entirely stop the contraction of the heart, is shown:—

—	Stimulating	Reducing	Paralysing
Ether	1 per cent.	1·5 per cent.	2 per cent.
Ethidene dichloride	$\frac{1}{20}$th " "	$\frac{1}{10}$th " "	$\frac{1}{5}$th " "
Bromide of ethyl	$\frac{1}{20}$th " "	$\frac{1}{8}$th " "	$\frac{1}{4}$th " "
Chloroform	$\frac{1}{30}$th " "	$\frac{1}{20}$th " "	$\frac{1}{10}$th " "

A qualitative difference was also shown. Ether and ethidene very much resembled one another. The relaxation after each contraction was complete. With chloroform and bromide of ethyl, however, a marked difference was observed. The heart showed a great tendency to contract spasmodically round the canule. So marked was this, that it was difficult to pass the nourishing fluid through the heart, in order to wash out the drugged fluid. This action was never observed with ether and ethidene when the heart had been fairly under their influence. It was noticed in more than one case, however, that the heart became spasmodically contracted round the canule immediately on receiving the first stimulating dose of the drug. This occurred with ether as well as with chloroform. With ether, however, it rapidly passed off, and did not recur after the full influence of the anæsthetic was felt. It did not so readily pass off with chloroform. The author suggested that such an action on the human heart might account for some deaths from chloroform before any quantity of the drug had been given.

The heart recovered speedily from the influence of ether, but slowly from chloroform. Ether was found not to be cumulative; but this could hardly be said so decidedly of chloroform.

The mixture of chloroform, alcohol, and ether (called the A.C.E. mixture) was tried. It seemed to paralyse the heart even more rapidly than chloroform alone, and none of the evil effects of chloroform seemed to be diminished. [Tracings were shown, and a demonstration of the action of ether on the frog-heart was given.]

2. *On the Action of Cold on Microphytes.*[2] *By* John G. McKendrick, *M.D., LL.D., F.R.S.*

3. *On the Action of Ozonised Air upon Micro-Organisms and Albumen in Solution.* *By* J. J. Coleman, *F.C.S.*

The author described a number of experiments conducted by him in conjunction with Professor McKendrick, F.R.S., being supplementary to their joint investigation upon the influence of cold upon microphytes. Air artificially impregnated with ozone by means of a Ruhmkorff coil, so as to contain a much larger percentage of ozone than any natural atmospheric air, was passed continuously through a 1 per cent. solution of white of egg placed in a glass flask, the inlet and outlet tubes of which were carefully plugged with cotton wool previous to commencing and during the experiments.

It was found from various experiments that a stream of air passed through 100 c.c. of the liquid for 30 hours containing an amount of ozone equal in

[1] Details as regards Ether only found in a paper, 'Ueber die Wirkung des Ethers auf das Frosch-Herz.' *Du Bois-Reymond's Archiv für* 1881.

[2] See *Proceedings of the Royal Institution of Great Britain* and *Proceedings of the Philosophical Society of Glasgow*, 1884–85.

weight to the albumen in solution failed in producing the slightest trace of oxidation, and that the ozonised air passed through the liquid quite unaltered.

During the course of the experiments, and for six days following, the development of micro-organisms ceased; but at the end of that time, and notwithstanding the cotton wool plugs, the liquid became slightly turbid from the presence of organisms.

As dilute hydrogen peroxide is without action upon albumen, the conclusion seems inevitable that albumen is practically indestructible by any atmospheric agency without previous splitting up by micro-organisms, and further that whilst micro-organisms cannot develop, and are probably killed in an ozonised atmosphere, their spores are not easily destroyed by its agency.

These results confirm the surmise of the late Dr. Angus Smith, that putrefaction is a necessary preliminary to oxidation in all cases of *natural* river purification.

---

4. *A new Theory of the Sense of Taste.* *By* Professor J. Berry Haycraft.

The author showed that 'quality' in this sense depends upon the nature of the atoms found in the sapid molecule. A study of the periodic law demonstrates that similar tastes are produced by combinations which contain elements, such as lithium, sodium, and potassium, which show a periodic recurrence of ordinary physical properties. Among the carbon compounds, those which produce similar tastes are found to contain a common *group* of elements. Thus organic acids contain the group CO, OH; the sweet substances CH_2, OH. There is no relation between quality of taste and gross molecular weight, except that substances either of very small or very great molecular weight are not tasted at all.

SATURDAY, SEPTEMBER 12.

The following Papers were read:—

1. *On a Model of the Whale.* *By* Captain Gray.

---

2. *On the Hybridisation of Salmonidæ at Howietoun.* *By* Francis Day, *C.I.E.*

Among the papers on the fishes of the British Isles, which have from time to time appeared in the 'Proceedings of the British Association,' are several respecting the Salmonidæ. Most of these communications have been restricted to investigations into species and their distribution, or questions as to their artificial propagation, but none to hybridisation.

During the last eleven years, Sir J. R. Gibson-Maitland, at Howietoun, near Stirling, has devoted much attention to this subject, and gone to great expense in order to efficiently carry out the many experiments he has instituted, while he has likewise afforded me facilities for personally watching many of them, and furnished me with data as well as with specimens. This subject, which is among the most interesting problems of fish life, I have selected for communication to this meeting; for, although only some conclusions have been arrived at, I cannot resist feeling that such important Scottish experiments ought to be recorded, so far as they have gone, in the 'Proceedings' of this Association, now that it is holding a meeting in the country were they are being carried out.

Willoghby and Ray, as early as 1686, alluded to hybrid fishes, and Pennant (edition 1812) observed 'hybrid fish, for that such exist those persons who have paid most attention to the subject in ichthyology have not a doubt.'

When we consider that the ova of teleostean or bony fishes have, as a rule, to

be fertilised by the milt of the males diffused in the surrounding water, it is not difficult to believe that this fluid from the male of one genus might come into contact with the eggs from fish of another species, genus, or even family, and a hybrid offspring be thus occasioned. But the size of the micropyle of the ovum and that of the spermatozooid of the milt must be of conforming capacities or fertilisation would be a physical impossibility.

Fraisse alludes to a hybrid offspring between a brook-trout and a burbolt, or between fishes belonging to two distinct families; and in the 'Bulletin of the United States Fish Commission' in 1882 is an account of a hybrid between a fish pertaining to the herring family, *Clupeidæ*, and the striped bass, *Roccus lineatus*, a percoid which supplied the milt.

Livingston Stone observed in 1869 that he had crossed the yellow perch, *Perca flavescens*, with the glass-eyed perch, *Lucioperca*, when the embryos continued to develop until the seventh day, and then ceased to do so. Crosses have also been effected between the golden tench, *Tinca vulgaris*, and the common carp, *Cyprinus carpio*; the rudd, *Leuciscus erythrophthalmus*, and the gold carp, *Carrassius auratus*; the roach, *Leuciscus rutilus*, and the bream, *Abramis brama*; between the rudd and the bream; the chub, *Leuciscus cephalus*, and the bleak, *Alburnus lucidus*, &c.

Restricting ourselves to the recorded instances respecting hybridisation among the Salmonidæ in Great Britain, we find it observed upon by Willughby in 1686, when it was remarked that he was persuaded that the salmon and the various forms of trout interbreed; and many authors in this country have erroneously asserted that par were hybrids, until this question was set at rest by the fish culturists. Mr. Shaw, in 1841, observed that his 'experiments with the ova of the common trout and salmon had been quite successful;' that 'those produced between the salmon and the salmon-trout appeared to partake more of the external markings, silvery coating, and elegance of form of the par than any of the others. Those produced between the salmon and the common trout, and between the common trout and the salmon-trout, had in every respect more the appearance of the common trout than the former.'

The Ashworths, in 1853, remarked upon rearing offspring from the ova of trout fecundated by salmon milt. Davy, in 1858, also observed that Mr. Reynolds mixed together the roe of the lake-trout and the fluid milt of the char, and in seventy days young fish were hatched.

The ponds at Howietoun, where the breeding of the Salmonidæ are carried on, are thirty-two in number, constructed in accordance with whether they are intended to accommodate breeders or for rearing purposes; the whole being surrounded by a strong paling five feet high, with an iron spike six inches in length surmounting each post.

The first question which seemed to require being settled was whether, if salmon were crossed by trout, a sterile or a fertile race of hybrids would result? If they were sterile, would they or would they not possess anadromous instincts? It is evident that, could a breed of fish be procured that would not migrate seawards, such would prove most valuable in the upper waters of rivers, as the Thames, which is so polluted in its lower reaches as to be practically impassable to the finny races, and consequently cannot be frequented by anadromous forms.

Leuchart refers to salmon ova, in 1878, having been fertilised by trout milt. No mention is made of the progeny attempting to spring out of the pond in which they were confined, while ova and milt were procured from these hybrids when twenty-two months of age.

At Howietoun some salmon eggs were hatched in March 1881, and on November 29, 1883, or at thirty-two months of age, milt was procured from these fish; but it was not until November 7, 1884, or when forty-four months old, that ripe eggs were furnished by any of these fishes. It would thus appear that the period at which the pure salmon breeds is at least a season later than the trout when kept under the same conditions.

December 24, 1881, about 20,000 Lochleven trout ova were fertilised at Howietoun with salmon milt, and these hatched on March 9, 1882. From time to time some of these hybrids were examined, but none showed signs of breeding until

May 1885, when they commenced springing out of the pond; and on one being opened it proved to be a female with the eggs developing, and had it lived it would evidently have bred this winter when about forty-four months of age, or at a similar period to the female smolt of the pure salmon. But, unfortunately, owing to the severe drought which the country suffered from during the last summer, the stream ceased to give an adequate supply, and all but two of the 144 fish were found dead. Milt and roe were developing in almost all, and although this experiment has not been successfully completed, it so far demonstrates that hybrids between the male salmon and female trout are fertile at the same period as are pure salmon.

In Leuchart's case the trout was the male element, and his fish commenced breeding near the end of their second year, as is the case with trout. At Howietoun, where the salmon was the male element, the hybrids would have commenced breeding at about the same period as in the salmon. It would therefore seem probable that the male elements in both cases had been prepotent, and also that when the male element in the hybrid has been the anadromous salmon, the young at the breeding season attempt to migrate seawards, and they have not lost their anadromous instincts.

Some more hybrids, similar to the foregoing as regards parentage but only one year old, are at Howietoun, and it is hoped will in due course arrive at maturity.

A set of experiments were likewise instituted at Howietoun into the question of whether the age of the male parent has any direct influence on the health of the hybrid progeny. On November 29, 1883, about 4,500 eggs from a Lochleven trout of the season of 1875 were milted from a salmon par thirty-two months old. The eggs hatched well, but the majority of the young were affected with dropsy of the yelk sac, from which nearly all succumbed before the end of the year. That this dropsy was owing to deficiency in vitality is rendered probable by an experiment I tried at Cheltenham in 1884–5, when out of about five hundred young trout only one had dropsy of the yelk sac, and the egg from which it had been hatched had been kept in brackish water in order to ascertain whether that would preclude its hatching.

On November 11, 1884, about 12,000 eggs of Lochleven trout were milted from a salmon smolt a year older than in the last experiment. About 9,500 hatched on January 28, but many died of dropsy of the sac; and on June 19 about 5,000 healthy young ones were turned into a rearing pond. Dropsy in this experiment did not set in quite so rapidly or severely, neither were so many proportionately affected. In this instance, again, there was evidently deficiency of vitality, probably due to the age of one of the parents, and if so that must have been the male, which was forty-three months old.

Several other experiments were made, but with similar results, which would seem to demonstrate that a sickly or feeble offspring results from crossing young salmon, as par or smolts, with mature trout, no matter how vigorous the latter may be. As a corroboration of this opinion the following experiment, also made at Howietoun, may be quoted. November 14, 1884, about 500 eggs, each having a diameter of 0·17 of an inch, were taken from a Lochleven trout not quite two years old. These were fertilised from another of the same race, but older. But only about a dozen hatched on January 28, 1885, and of these seven lived and were turned out into one of the rearing ponds. This is a very instructive experiment, as not merely demonstrating the small size of the eggs given by young mothers, but likewise as pointing out that such as are obtained from young parents either hatch indifferently or even fail to do so, simply due to deficiency of vitality on the mother's side. This experiment must likewise cause one to hesitate before expecting the eggs of two-year-old hybrids to be good hatchers, another season at least being necessary in order to arrive at satisfactory deductions on this head.

Intercrossings have likewise been carried on at Howietoun between trout and char. On November 15, 1882, about 2,000 eggs of the Lochleven trout were fertilised from the milt of the American char (*Salmo fontinalis*). About one in six failed to hatch, while monstrosities were numerous among the progeny. Some were blind with one or both eyes, others had bull-dog malformations of the snout,

while more or less albinoism existed in such as had the sight of both or of only one eye affected. The general colours of these hybrids were yellowish shot with purple, and reticulated with irregular black bands, spots, and markings on the body, but most closely spotted along the upper surface of the head and back. Dorsal fin yellow, with spots and bands; pectorals black-tipped; anal with its first three rays white, the fin behind this being stained with dark grey; caudal dark edged, and having a few indistinct bars at its base. The colours of the male parent or of the American char predominated over those of the female or Lochleven trout. On November 12, 1884, some males were found to be ripe, but the females not quite so. In this instance, as in others, the males were most forward, while the age of these fish was about two years, rendering it evident that both eggs and milt may be expected in a hybrid between a trout and a char in its second year. The foregoing experiment was repeated on November 29, 1883, and about one in seventeen of the eggs failed to hatch.

The last experiment was now reversed. November 15, 1882, 8,000 eggs of an American char were fertilised from a Lochleven trout. About one in three failed to hatch. The young were much deformed, many had their spines crooked, and in some there was atrophy of their posterior portion with a deficiency of fins generally, especially of the caudal. The colours of these hybrids closely resembled those seen in the preceding experiment, or those of the female fish, the American char predominating over those of the male parent, the Lochleven trout. About eight of these fish still survive.

The next set of intercrossing were between the British and American chars. November 15, 1882, about 9,000 ova of an American char were milted from a char from Loch Rannoch. The mortality among the eggs was nearly one in four and three-quarters. There were no considerable number of monstrosities or malformations. The colours were of a beautiful iridescent purple, with thirteen transverse or par-bands along the sides, the whole of the body being sprinkled with light spots. The front edge of the dorsal, ventral, and anal fins were white, as was also the outer pectoral ray. There were a few dark marks along the base of the dorsal fin. In this experiment the colours mostly partook of those of the male parent or Scotch char, which largely predominated over those of the female parent or American char. By November 12, 1884, the majority seemed to be in a breeding condition.

The final series of hybridisation experiments which I propose alluding to in this paper were intercrossings between the foregoing hybrid races; again, however, drawing attention to the fact that, as these fish were all in their second season, such a young age may account for unsatisfactory results, but each additional year will doubtless be productive of increased interesting facts.

November 12, 1884, 146 eggs were obtained from a hybrid between the British and American chars, and milted from another of the same breed; only six hatched, and these died prior to the period for turning the young into the rearing ponds.

December 6, 1884, 600 eggs, each about 0·15 of an inch in diameter, were obtained from a hybrid between the British and American chars, and milted by one of the same race. Only about fifty hatched on February 23, and of these a single one survived to be turned into a rearing pond.

These hybrids were likewise crossed with the original parent stock. November 12, 1884, 1,350 eggs of a Lochleven trout were milted from a hybrid offspring from the Lochleven trout, crossed by the male American char. About twelve of the eggs 'eyed,' but only three of these embryos arrived at a full size, but even they failed in hatching out, dying in their shells.

November 12, 1884, 4,500 eggs taken from two Lochleven trout were milted from a hybrid offspring from the British and American chars. 1,292 eggs were picked out dead from the hatching trays, 1,568 were unimpregnated, only a little more than one-third hatched, and among these were many deformities and a few dropsies. A great mortality occurred among these young fish, and only 320 lived to be turned into the rearing pond.

It would appear from the foregoing that the following conclusions may be more or less drawn:—

1. Salmon and trout, trout and char, and different species of char, may interbreed and give rise to fertile hybrids.

2. Hybrids raised from Lochleven trout eggs fertilised by salmon milt breed in their fourth year, similar to young female salmon kept under the same conditions.

3. The anadromous instinct is not lost in these trout and salmon hybrids.

4. Judging from the period of breeding in the foregoing hybrids, the male element is prepotent.

5. In hybrids raised from Lochleven trout eggs fertilised by the milt of the American char, the male element would appear to be prepotent, if we judge simply by the colour of the offspring.

6. In hybrids raised from American char eggs fertilised by the milt of the Lochleven trout, the female element would appear to be prepotent, if we judge simply by the colour of the offspring.

7. In hybrids raised from American char eggs fertilised by the milt of the British char, the male element would appear to be prepotent, if we judge simply by the colour of the offspring.

8. In all instances of hybridisation between different species, as between salmon and trout, or trout and char, numerous instances of malformation and great mortality occur among the offspring, but much less when two forms of char are intercrossed.

9. In intercrossing hybrids both the eggs and milt were found to be fertile, but the malformations and mortality very great. The parents, however, at Howietoun are not yet of sufficient age to admit any safe deductions on this head.

10. The age of the parent exercises great influence on the vitality of the offspring, for, when very young, we may expect a large percentage of malformations, as well as dropsy and other diseases, in the offspring.

---

3. *On the Identification of the British Mosses by their Distinctive Characters.* *By* Mrs. Farquharson, *F.R.M.S.*

Since the appearance of Dr. Braithwaite's 'British Moss Flora,' no advanced student of mosses can complain of the want of an adequate manual in the British language, yet no one who has commenced the study of this order of the *Cryptogamia* can have failed to experience some difficulty in the earlier stages of his work. Without wishing to depreciate the several valuable works on the subject, I have noticed the absence of any work which deals with the distinctive characters of mosses, apart from those of a general nature. I feel sure the want is much felt by young students, who find it difficult to classify mosses especially. The plan which I have found useful is to separate the essential differing characters of each genus in this manner:—

Andreæa.—The capsule splitting into valves, but adhering at its apex.

This character alone isolates this genus from all others. It is also a help to have a plate or drawing near the description of each genus.

The species in like manner. I have found it most desirable and useful to ascertain one (if not more than one) distinctive character, which can be readily carried in the mind's eye, whereby a species can be recognised from its fellow in the same genus.

4 *On the Flora of Caithness.* *By* James F. Grant.

At present there exists no published flora of Caithness, beyond the plant-list in 'Topographical Botany,' and the various lists printed in the different reports of the Botanical Exchange Club and of the Botanical Record Club. The late Robert Dick, of Thurso, made an exhaustive examination of the flora of Caithness; but he left no MS. notes, and his herbarium contains few Caithness specimens; and such as there are seldom have any locality affixed. Owing to the absence of woods and forests, Caithness is singularly deficient in many of the more common British wild plants; and, as the county is generally low-lying, there is a paucity of alpine

forms, such as do occur frequently growing on the sea cliffs, e.g., *Saussurea alpina* (D.C.). The most characteristic plant of the Caithness cliff-pastures is *Primula Scotica* (Hook.), which occurs very abundantly all along the east and north coast of the county. It flowers three times a year, and is generally found in conjunction with *Scilla verna* (Huds.), and occasionally with *Oxytropis Halleri* (Bunge). Of the flora of the moist, sandy 'links,' or downs, *Juncus Balticus* (Willd.), *Carex incurva* (Lightf.), *Carex pauciflora* (Lightf.), *Blysmus rufus* (Link), and *Viola Curtisii* (Forster), var., are typical representatives. *Carex aquatilis* (Wahl.) var. *Watsonii* is common to nearly all the streams of the county. A *Carex* new to Britain, viz., *Carex salina* (Wahl.) var. *Kattegatensis* (Fries)—the Norwegian 'saltvands star'—was discovered last year near the mouth of the Wick River. It is somewhat like *C. paludosa* (Good.) in appearance, with long, aristate, and dark purple-coloured glumes, and is a native of Iceland, Lapland, and Scandinavia. Critical genera, such as *Salix* and *Hieracium*, are well represented in Caithness, but there are few *Rosæ*. The nature of the surface is not favourable to the growth of aquatic plants. *Nuphar pumilum* (Sm.) and several Potamogetons and Charæ may be got on some of the lochs. There has this year been made out in Caithness a new British grass, *Calamagrostis strigosa* (Hartm.) —the Scandinavian 'stivhaaret ror'—which is somewhat like *C. stricta* (Nutt). It grows in marshy ground near Castletown. *Hierochloa borealis* (R. and S.), discovered by Dick, has almost disappeared from Caithness for the last twenty years, but this year it has been observed on the Thurso River many miles up. The northern and exposed position of Caithness causes slight differences of form and structure in many plants, compared with more southern forms.

5. *On Chinese Insect White Wax.* *By* A. HOSIE.

The author began with a reference to the European and Chinese writers who mention Chinese insect white wax. He goes on to say that, although the province of Ssu-chuan, in Western China, where he has been stationed for the last three years, is the chief wax-insect and wax-producing country in the empire, insects and wax are found in other provinces. Mr. Hosie was called upon by the Foreign Office to collect for Sir Joseph Hooker specimens connected with, and all possible information on, the subject of this industry, and he states that the present paper is a revision, with additions, of a report already published in a Parliamentary paper in February last. He describes the insect-producing country, the tree on which the insects are propagated, the insects themselves, and their transit from the valley of Chien-chang, their breeding-ground, in the west of Ssu-chuan, across the mountains to Chia-ting Fu, the habitat of the wax tree. This tree is then described, and details are given of the treatment of the insects, their suspension on the trees, the depositing of the wax, and of a parasite on the insects. The method of removing the wax from the branches of the tree and of preparing it for market is then explained. The author then detailed the result of an examination of the insects after the wax has been fully deposited, finally passing to the annual quantity of insect white wax produced, its value and uses.

6. *On the Existence of Cephalopoda in the Deep Sea.* *By* W. E. HOYLE.

Evidence of the existence of Cephalopoda in the deep sea has hitherto been wanting, but a certain amount seems to be now forthcoming in the case of the genera *Cirroteuthis*, *Bathyteuthis* and *Mastigoteuthis*.

None of these forms (except one species of *Cirroteuthis* from the arctic seas) were known prior to the days of deep sea investigation, nor have any of them been taken by a surface net, nor by any other means than a dredge or trawl which had been down into deep water.

The genus *Bathyteuthis* seems to present structural peculiarities fitting it for an abyssal existence, in certain of which it agrees with *Mastigoteuthis*, although they differ markedly in other respects.

7. *On the Echinoderm Fauna of the Island of Ceylon.* *By* Professor F. JEFFREY BELL, *M.A.*, *Sec.R.M.S.*

The author gives an account of the remarkable advance in our knowledge of the Echinoderm fauna of the island of Ceylon. Till 1882 some four species were known from the island; forty-five are now known, and some six Holothurians remain to be investigated. These advances are due partly to the collection of Professor Haeckel, but chiefly to the industry and activity of Dr. W. C. Ondaatje.

MONDAY, SEPTEMBER 14.

The following Report and Papers were read:—

1. *Report on the Aid given by the Dominion Government and the Government of the United States to the encouragement of Fisheries, and to the investigation of the various forms of Marine Life on the coasts and rivers of North America.*—See Reports, p. 479.

---

2. *On the Size of the Brain in Extinct Animals.* *By* Professor O. C. MARSH.

The main points were the following:—

1. All Tertiary mammals had small brains.
2. There was a gradual increase in the size of the brain during this period.
3. This increase was confined mainly to the cerebral hemispheres, or higher portion of the brain.
4. In some groups, the convolutions of the brain have gradually become more complex.
5. In some, the cerebellum and the olfactory lobes have even diminished in size.
6. There is now evidence that the same general law of brain growth holds good for birds and reptiles from the Jurassic period to the present time.

To these may be added the following:—

7. The brain of an animal belonging to a vigorous race fitted for a long survival is larger than the average brain of that period in the same group.
8. The brain of a mammal of a declining race is smaller than the average brain of its contemporaries of the same group.

This question is more fully discussed in the author's monograph on the 'Dinocerata,' just published by the United States Geological Survey.

3. *On the Systematic Position of the Chamæleon, and its Affinities with the Dinosauria.* *By* Professor D'ARCY W. THOMPSON.

---

4. *On the Hind Limb of Ichthyosaurus, and on the Morphology of Vertebrate Appendages.* *By* Professor D'ARCY W. THOMPSON.

A skeleton ascribed to Ichthyosaurus platyodon in the Anatomical Museum of Edinburgh University exhibits certain remarkable peculiarities in the hind-limb, which perhaps render it the most primitive limb known in vertebrates above fishes.

In the first place, the femur has articulated with it three bones, identifiable as tibia, intermedium, and fibula, as in Marsh's *Sauranodon,* and as in the limb

figured as *Pliosaurus portlandicus* by Owen ('Fossil Reptiles'), but ascribed to *Plesiosaurus Manseli* by Hulke (Q. J. G. S. 1883, Suppl. p. 52). This therefore is an additional proof that the primary location of the intermedium is in the 'propodial' segment of the limb.

The limb of Sauranodon contains in its next segment four bones, and so probably, to judge from its articular surfaces, did that of *Pliosaurus*. That is to say, granted that the bones already mentioned are rightly identified, we have in the proximal segment of the tarsus a *tibiale*, a *fibulare*, and *two centralia*. In the Edinburgh *Ichthyosaurus* we have *one centrale* only; and, moreover, we have again in the next succeeding segment *three bones* only, whereas we have five in the corresponding region of Marsh's *Sauranodon*. So far then we have three longitudinal series of bones, and these three rows continue distinct to the distal extremity of the limb. Two other longitudinal series of bones exist: one, a somewhat irregular series of rounded ossicles, is applied to the tibial side of the limb, commencing immediately distal to the tarsus, but not directly articulated with it; the other, commencing at the same level, is inserted between the median and external or fibular row. If we may consider the ground-plan of the limb apart from these last two series, we have here simply three longitudinal series of bones, symmetrically articulated with the extremity of a basal segment. While the limb of Sauranodon seemed to be a weighty argument in support of Gegenbaur's theory of the primitively double nature of the centrale, the present example seems to me a still more potent argument against it; for the common type of Ichthyosaurian limb is undoubtedly intermediate between that of the present example and the typical cheiropterygium of the higher vertebrates; and we pass from our present case to the typical Ichthyosaurus by transverse cleavage of the centrale, and the apportionment of its outer moiety to the interstitial digit.

It is equally easy to pass downwards from this limb to the fin of fishes. Assuming the femur to represent the basipterygium, we have here three basalia, which by elongation and segmentation may be supposed to have given rise to the distal portion of the fin. And the limb has a great though not genetic resemblance to that of Polypterus, where the basalia are reduced to four, or as in one specimen which I have dissected, actually to three. It need hardly be said that this view is wholly incompatible with Gegenbaur's theories; and indeed Wiedersheim has confessed that if the limb of Sauranodon be confirmed, it must lead to the complete recasting of our idea of the vertebrate limb. But it remains to be seen whether the Dipnoan fin is explicable on this hypothesis. In the fin of *Protopterus* the segment articulating with the pelvis, is, I take it, a true basipterygium. To it I find attached two small nodules of cartilage, between which is the main axis of the fin: here we seem to have three basalia, one only of which is elongated or segmented, as are all in our Ichthyosaurus. While in Ceratodus we are reduced to supposing that this one segmented ray has branched laterally, to give breadth and strength to the fin.

---

5. *On the Origin of the Fishes of the Sea of Galilee. By* Professor EDWARD HULL, *LL.D., F.R.S.*

When preparing a memoir for the Palestine Exploration Society on the physical history of Arabia Petræa and Palestine I was confronted with two biological problems: one, on the origin of the fauna of the Sea of Galilee (or Lake of Tiberias); the other, on the cause of the extreme dissimilarity between the faunas of the Red Sea and Mediterranean, notwithstanding the ascertained fact that the seas themselves have been physically connected within very recent times. With the former problem I propose here to deal as far as the fishes are concerned; with the latter I shall deal presently.

The abundance of the fishes which inhabit the waters of the Sea of Galilee is known both from sacred and secular history, and has been testified to by several recent observers. The characters and habits of these fishes have also been ably dis-

cussed and illustrated, especially by Canon Tristram[1] and Professor L. Lortet,[2] from which it has been determined that nearly one-half of the species are peculiar to the lake and its tributaries; while of the rest only one—namely, *Blennius lupulus*—belongs to the ordinary Mediterranean fauna; two others—namely, *Chromis Niloticus* and *Clarias macracanthus*—are found in the Nile; seven other species occur in the rivers of South-western Asia; and ten more are found in other parts of Syria. Tristram considers that this assemblage points to a close affinity of the fauna of the Jordanic basin with that of the rivers of Tropical Africa (Æthiopian); but what most strikes the observer is perhaps the number of species special to Jordanic waters, sixteen out of a total of thirty-six species being peculiar. This view seems to be borne out also by an analysis of the molluscous forms, which are for the most part also peculiar, for no less than sixteen species of *Unio* are special to Jordanic waters.[3] Assuming that the forms which are common to Jordanic and other waters have been distributed in a manner similar to that by which we have to account for the distribution of lacustrine forms in other parts of the world, we have yet to account for the presence of the forms which are special and peculiar.

This leads to a consideration of the manner in which the Jordanic basin was first formed and afterwards modified; and without entering here into this wide question, which I have endeavoured to deal with in the memoir above referred to, I may be allowed to summarise my conclusions somewhat as follows:—

In the first place, it must be recollected that as the whole region on both sides of the Jordanic valley was originally overspread by strata of the Eocene period (known as the *Nummulitic Limestone*), this region formed the floor of the ocean down to the close of the Eocene period; the only possible lands in the district may have been those of the crystalline rocks of the Sinaitic group of mountains.

The Geological period which succeeded, that of the Miocene, was that in which land first appeared in the Palestine area. The bed of the sea was locally elevated into dry land, but at the same time most of the leading physical features by which that land is now diversified were traced out and finally determined. Chief amongst these was the line of the great Jordan-Arabah depression—marked out by a line of fault or displacement of the strata, ranging from the slopes of the Lebanon on the north to the Gulf of Akabah on the south. It seems to me probable that as the land on either side of this depression was being elevated, the displacement of the strata on either side of the great fault was also proceeding, and the floor of the sea was subsiding along the line of the Jordan valley. An inland lake of considerable extent was thus formed, whose waters were first derived from those of the ocean itself, in which were enclosed the fishes and mollusks and other forms which inhabited these waters themselves. There are good grounds for believing that once the lake was enclosed and shut off from the outer sea by a barrier of land, it was never again physically connected with the outer sea. The saddle of the Arabah valley, rising some 600 feet above the highest limit to which the waters of the old Jordanic lake ever ascended, would have proved an effectual barrier towards the south.[4] Towards the west the barrier would have been much more elevated. Hence the living forms in the waters of the inland salt lake became isolated from those of the ocean, and had either to adapt themselves to their new conditions or to die out.

We may suppose that the first to disappear would be the corals, crinoids, and starfishes. On the other hand, fishes, mollusks, and crustaceans, having greater powers of adaptation, would in many cases survive. Meanwhile the law of 'descent with modification' would now come into operation, and we may suppose that throughout the Miocene and Pliocene periods the process of modification in form, colour, and habit gradually proceeded. The fittest forms would survive, and

[1] 'Fauna and Flora of Palestine,' preface, p. xii, *Mem. Palestine Survey* (1884).

[3] Tristram, *ibid.* p. 178. The mollusks have been also recently described by M. A. Locard, *Malacologie du Lac de Tibériade* (1883).

[4] See *Mount Seir, Sinai, and Western Palestine*, pp. 95 and 99, &c.

differentiation between those of the outer and inner seas, resulting, as we have seen, in almost an entire specific change, was effected.

The above view seems in accordance with recent observations regarding the adaptability of many marine forms to new lacustrine conditions, provided the process of change is sufficiently gradual. Professor Sollas, whose memoir on 'The Origin of Fresh-water Faunas'[1] is very suggestive, arrives at the conclusion that, as the conversion of comparatively shallow continental seas into fresh-water lakes has taken place on a large scale several times in the history of the earth, this has been accompanied by the transformation of some of the marine into fresh-water forms. The Jordan valley lake, originally salt, has shrunk back into two or three lakes connected by a river. The Dead Sea alone remains salt and lifeless. The waters of the Sea of Galilee are fresh, and teem with life. In reply to my inquiry whether the above views would harmonise with his own, Professor Sollas writes: 'I have always regarded the curious fishes of the Sea of Galilee as evidence of a previous marine communication, but it never occurred to me to speculate as to the age of that connection. If this sea (that of Galilee) were stocked from the Eocene ocean it would fit in very well with the history, as I believe it, of other fresh-water faunas.' It is gratifying to me to have the concurrence on this point of so able an authority. I conclude, therefore, that the special forms of fishes now inhabiting the Sea of Galilee are the descendants of those which lived in the Eocene ocean.

---

6. *On the Cause of the Extreme Dissimilarity of the Faunas of the Red Sea and Mediterranean. By* Professor EDWARD HULL, *LL.D., F.R.S.*

The author pointed out that the faunas of these seas have descended from the forms which lived in the Eocene Ocean. In the succeeding Miocene epoch, when the lands rose from the waters, the Mediterranean area was cut off from that of the Red Sea, and as different conditions would be thus brought about, especially in the case of temperature, the faunas would develop independently in both seas. This process of development and differentiation went on throughout the Miocene period and down into the Pliocene, when the lands were again submerged to a depth of 220 to 250 feet, and a connection of the two seas was re-established. But the depth of water over the connecting strait not being greater at its minimum than about 200 feet, although allowing a commingling of the littoral and shallow water forms, would have been insufficient to bring about a general community of species, especially those inhabiting the deeper waters on both sides, and when the land again rose, and the isthmus was established, the forms which had crossed from sea to sea would afterwards die out. From this it has resulted that the faunas of the Mediterranean and Red Seas are almost entirely dissimilar, only 18 species, according to Professor Issel, being common. It would be an interesting inquiry, which of these faunas more resembles the original Eocene stock.

7. *On the Morphology of the Human Arterial System. By* Professor A. MACALISTER, *F.R.S.*

---

8. *On the Viscera of* Gymnotus electricus. *By* Professor CLELAND, *M.D., F.R.S.*

Independent of its electric organs, this fish has a number of remarkable internal peculiarities. The curious spongy protuberances of the mucous membrane of the buccal cavity are well known to zoologists. The two swimming bladders are remarkable for their relation to the kidneys; the anterior swimming bladder being a small structure between their anterior extremities, and the larger posterior swimming bladder being situated altogether behind their united hinder ends, while the duct of the latter ascends by the left side of the renal outlet, to be joined by the

[1] *Scientific Trans. Royal Dublin Society*, vol. iii. (ser. II.).

duct of the other bladder before entering the gullet. The pylorus also is remarkably contracted. But the most striking and altogether curious arrangements are seen on the ventral wall of the abdomen. The intestine passes forward the whole length of the abdominal cavity to the vent, and on its under side is a long renal duct as wide as itself, and opening immediately behind the vent; while, opening into this duct close to its outlet, are the ducts of the two ovaries, which lie one on each side, their morphologically anterior extremities placed posteriorly, as if in process of development these organs had been pulled round from their proper subvertebral position until completely inverted.

9. *On the Spiracle of Fishes in its relation to the Head, as developed in the Higher Vertebrates.* *By* Professor Cleland, *M.D., F.R.S.*

A very extraordinary mistake can be shown to be prevalent among embryologists, to the effect that the spiracle corresponds with the tympanum and external auditory meatus in the higher vertebrates. This is not the case. The spiracle is pre-oral; the tympanum is post-oral. The apparent sequence of the spiracle with the branchial clefts occurs, as Balfour described it, in the embryo of the dog-fish; but for all that, and although it has rudimentary external gills attached to its margins in the embryo, it is in front of the mandibular arch and above the maxillary lobe. Between the middle and lateral frontal processes is the nostril; between the lateral frontal process and the mandible is the space into the upper part of which the eyeball projects, and from which the lachrymal duct is developed; while between the first and second visceral lobes is the external ear; and it is highly probable that the upper part of the first branchial cleft is homologous with the clefts in front of and behind the lateral frontal process. Thus a certain amount of homology would exist between the spiracle of fishes and the lachrymal duct.

---

10. *On the Tail of* Myxine glutinosa. *By* Professor Cleland, *M.D., F.R.S.*

The dorsal and anal fins of *Myxine* are continuous at the tail. They consist of numerous rays, which, when the integument is removed, are seen to be of fibrous structure imbedded in a thin membrane. But the inferior rays of the tail differ from the superior, in that the hindermost of them are supported by a triangular plate of cartilage about half an inch long, lying beneath the chorda dorsalis, and continued into about twenty-four longer or shorter processes. In front of them, at the anterior inferior angle of the triangle, is a small bifurcated process, ending in two slight dilatations, which support the hindermost pair of mucous glands. The triangular plate is of a variety of cellular cartilage allied to the structure of the chorda.

---

11. *On the Nucleus in the Frog's Ovum.* *By* George Thin, *M.D.*

The paper describes conditions of the nucleus as observed in ova of *rana temporaria*, between the stages of division into four segments, and that of the end of segmentation when the ovum has assumed a moniliform or mulberry appearance. The appearances described were those observed when sections of ova hardened in bichromate of potash had been stained by picro-carmine. They refer exclusively to changes which carmine-staining shows takes place in certain unformed constituents of the nucleus. In the paper the nuclear network is left out of consideration, the methods of preparation not having brought it satisfactorily under observation.

The conditions observed might be classified as follows: 1st. A *tablet nucleus*,[1] in which the distinctive carmine-staining was found associated with an unformed substance which infiltrates the yolk substance in certain parts of the segments.

[1] A literal translation of *Täfelchen*, the word used by Goethe. It is more appropriate than such terms as 'yolk granules,' &c.

That this is a stage of the nucleus is shown not only by the distinctive staining, but by the well defined nuclear area, the size of the latter and its relations to characteristic accumulations of pigment. In this stage the yolk tablets in the nuclear area are of the same size as those of the surrounding yolk substance of the segments. 2ndly. A *diffuse granular nucleus,* in which in the carmine-stained nuclear area there are imbedded minute yolk tablets smaller than those in the surrounding segment; and also frequently pigment granules. 3rdly. The *homogeneous nucleus* in which the nuclear substance stains homogeneously in carmine. It has distinct boundaries and contains neither yolk tablets nor pigment. 4thly. The *shrunk nucleus* in which a crescent-shaped shrivelled homogeneous substance represents the nucleus. The *shrunk nucleus* may occupy a small part of a hole which equals in area the usual size of a homogeneous nucleus. 5thly. Simple holes are found which from their size and relations to pigment correspond to the position of nuclei. Near these holes one or more *tablet nuclei* or *granular nuclei* are found in the segment.

Although the nuclei are generally found round, yet they are frequently found in various other shapes in the sections, for example, as narrow strips or as club-shaped and crescentic bodies.

The nucleus is sometimes found homogeneous at one part, and in the condition of the tablet or diffused granular nucleus at another, the granular or tablet condition being on the periphery of a round, or at the extremity of a fan-shaped nucleus.

The nucleus may be in direct contact with the substance of the segment, or may be separated from it by a perinuclear area. The perinuclear area may consist of minute breaking down yolk tablets, or may be constituted by a space filled with a homogeneous unformed substance, which does not stain in carmine, and which contains neither yolk tablets nor pigment.

Division of the Nucleus.—An elongated nucleus may be found divided transversely by a narrow line which is either unpigmented or contains pigment. This line may only partially extend through the nucleus. More frequently two nuclear areas are found connected by traces of carmine-stained nuclear substance sprinkled amongst the yolk tablets of the segment. Sometimes two tablets or granular nuclei, removed to a considerable distance from each other, are found linked by this carmine-stained substance. Frequently two such nuclear areas are found in an undivided segment without any such connecting link. Less frequently, two homogeneous nuclei are found close together in a space which is free from yolk substance or pigment; more than two newly formed nuclei may be found in a segment, three and even four being occasionally found. The nuclei may be completely divided and removed from each other before there is any trace of division of the segment.

Pigment.—There is a well-defined relation between accumulations of pigment and division of the nucleus. Pigment is found mixed with minute tablets in the granular nucleus. It may penetrate into the interior of a tablet nucleus in a fine line. In the other stages it is not found within the nucleus, but is found external to it, either in immediate apposition or separated from it by a perinuclear area. Pigment tracks may be traced directly from the periphery of the ovum to nuclei.

Pigment in relation to the Segments.—Pigment is found either equally diffused or collected in masses, or forming distinct rings, or around holes within the segments. Between the segments it may be found either as a single slender dividing line, or as a line which is split at intervals by a space, or it may traverse the segments in various directions in lines.

If, as may be taken for granted, the pigment itself is passive in the assumption of these forms, then its distribution indicates currents within the segment which have a special relation to the nucleus. These currents it is thus shown penetrate from the periphery to the nuclei, and in the tablet and granular stages they penetrate the substance of the nucleus. The accumulation of pigment around and outside the perinuclear area, and its disappearance from the nucleus, indicates a centrifugal current. There are thus in the segments both centripetal and centrifugal currents of which the nucleus is a centre.

The pigment has no causal relation in the nuclear changes, as they are found (more especially in the lower pole), in the absence of pigment.

Thus although the author has been unable to trace the detailed changes of karyokinesis in the division of the nuclei in the frog's ovum, he has observed appearances associated with a substance which stains in carmine, which to some extent harmonise with it. From a nucleus which has arrived at a certain stage a substance escapes into the surrounding part of the segments, and there becomes a centre of an area in which the yolk tablets are dissolved and a new nucleus forms, this nucleus passing through the various stages above described. The newly formed nuclei have the power of dissolving the yolk tablets, of assimilating the substance of the segment, of becoming the centres of currents which must have an influence on its nutrition, and which probably are intimately connected with the subsequent division of the segment that succeeds the development of the new nuclei. Nuclei observed in ova which were divided into four segments, and in those which after eighteen to twenty-four hours had developed into the moniliform or mulberry stage, show that the stages of development are the same in both instances.

12. *On the Structure and Arrangements of the St. Andrews Marine Laboratory. By* Professor McIntosh, *M.D., LL.D., F.R.S.*

The marine laboratory at St. Andrews was formerly a temporary wooden fever-hospital, 60 feet in length, but as it was only used for a few months some years ago, it was readily obtained for its present purpose. The accommodation consists of a tank-room, two work-rooms, a larger and smaller, an attendant's room, and engine house. Sea-water is obtained from the sea, which comes within a few yards of the laboratory, by means of a gas-engine, vulcanite pump, and pipes. The sea-water is first pumped into a granolithic underground tank, then to a high-level cistern, from which it runs by gravitation through the tanks. The latter are at different levels, and various supplementary vessels are easily added as required by resting them over the tanks and leading the sea-water into them by india-rubber tubes. The situation of the laboratory, which is on a narrow tongue of sand between the harbour and the sea, is most favourable, since the fishing-boats supply many interesting specimens on the one hand, and the beach is rich in marine life, both amongst the rocks and in the sand.

---

13. *Remarks on the work at the St. Andrews Marine Laboratory during nine months. By* Professor McIntosh, *M.D., LL.D., F.R.S.*

Amongst mammals several porpoises were examined, one a full-grown female 5 feet 2 inches long, recently delivered and full of milk. The rich yellow milk was examined by my colleague, Professor Purdie, who found in 100 parts by weight—water, 41·11; fat, 45·80; caseine, 11·19; milk sugar, 1·33 (?); mineral salts, 0·57.[1]

The detailed study of the development of many of the food fishes has been carried out by Mr. Prince. These include the cod, haddock, whiting, gurnard, common dab, and common flounder. The ova and development of other fishes were likewise examined, *e.g.*, rockling, lump-sucker, *Cottus scorpius,* Montagu's sucker, 15-spined stickle-back, herring, bib, ling, eel, skulpin, gunnel (Yarrell's blenny), wolf-fish, viviparous blenny, and glutinous hag. The young of many fishes from the rocks were kept under observation, and the food and parasites of others both in their young and adult condition received due attention.

The reproductive organs and development of various annelids, starfishes, ascidians (including *Pelonaia corrugata*), crustaceans, and mollusks (including the common mussel of Mr. J. Wilson), were studied more or less completely. Artificial fecundation had to be resorted to in the case of the common mussel by Mr. Wilson.

---

[1] *Chemical News*, Oct. 1885.

14. *On the Chemical Composition of the Milk of the Porpoise.* *By* Professor PURDIE, *Ph.D.*, *B.Sc.*

Professor McIntosh having kindly placed at my disposal a small specimen of milk which he extracted from the mamma of a porpoise, I have made an analysis of it, the results of which are given below:—

	In 100 parts by weight
Water	41·11
Fat	45·80
Albuminoids	11·19
Milk Sugar (?)	1·33
Mineral Salts	0·57

The milk was of a yellow colour and thick consistency; its specific gravity was almost identical with that of water.

The most remarkable point about the chemical composition of the milk as compared with that of other mammals, is the very high percentage of fat which it contains, a constituent which the habit of life of the cetacean no doubt requires in larger proportion. The quantity of material at my disposal being very small, the results of the analysis cannot pretend to great accuracy, and it must be noted that though the analysis represents the milk as containing a small quantity of sugar, the presence of that substance in it is doubtful. Having no more material at my disposal, I was unable to confirm my observation.

---

15. *On certain processes formed by Cerapus on Tubularia indivisa.* *By* Professor MCINTOSH, *M.D.*, *LL.D.*, *F.R.S.*[1]

The members of the domicolous subdivision of the amphipodous crustaceans are characterised by the very general habit of forming tubes of various kinds, which constitute dwellings as well as nests for the young. Others, again, excavate tunnels in tough clay or mud, like *Corophium*. The subject of the present remarks, which is apparently closely allied to *Cerapus difformis*, and very prettily barred with red on the antennæ, constructs groups of flexible tubes, which vary in diameter according to the size of the occupant, on stems of *Tubularia indivisa*, very much as Stimpson describes in his *Cerapus rubricornis* on the shores of Grand Manan. Instead of being formed, however, as Stimpson says, of 'fine mud and some animal cement,' those of the British species have, in addition, grains of sand, bristles, and spines of annelids, hairs of sea-mice, and many fine horny fibres apparently derived from the byssi of horse-mussels.

On the same stems of *Tubularia* are certain remarkable processes which project from the cœnœcium like branches. These filamentous structures are of a dull greyish hue (that of the mud), and are very slightly tapered distally. The basal region, however, is distinctly larger, especially where fixed to the zoophyte. Their length varies from three to four inches, and all seem to be incomplete. They are smoothly rounded, and resemble the fine muddy tubes secreted by certain annelids; but they are quite solid, and composed of the same constituents as the tubes abovementioned, though perhaps the foreign bodies such as bristles and spines are more conspicuous. These, moreover, are neatly arranged with their long axes parallel to that of the process, and especially abound towards the base of the filament, which thus is more rigid and tougher than the distal region, into the composition of which mud, sand, and the secretion chiefly enter. In consequence of this structure, the distal region slightly curves downward in the ordinary position in the water, while the proximal stands stiffly outward. These processes are generally fixed to the main stem of the *Tubularia*, though occasionally they spring from the

[1] This and the three following published with figures in the *Ann. Nat. Hist.* for December, 1885.

tip of a young example attached to the former, or stretch from the extremity of a parasitic sertularian.

These filamentous processes are usually at some distance from the nests or tubes of the crustaceans which climb actively on them. Whether they give them a larger area for the capture of prey in comparative security, or afford a more extensive surface for the temporary arrest of minute larval or other forms on which they feed, is unknown. It is probable, however, that processes so elaborate subserve some useful purpose to the species, and are not the result of mere purposeless formation.

16. *On a new British Staurocephalus.* *By* Professor McIntosh, *M.D., F.R.S.*

This form was first noticed in a small aquarium belonging to Mr. Sibert Saunders, at Whitstable, in 1884, and he kindly forwarded living specimens to the St. Andrews Marine Laboratory for examination. It is about 8 or 9 mm. in length by 1 mm. in breadth, including the bristles. The number of segments varies on each side of 30, exclusive of those without bristles. It is characterised by a horseshoe-shaped head furnished with a pair of short dorsal tentacles of two segments, and a similar pair on the ventral surface. Four eyes occur dorsally, one on each side behind the dorsal tentacle, and a smaller pair just in front of the nuchal fold. Each foot has dorsally a short cirrus, and ventrally a somewhat larger one, besides a long process of the setigerous region. Dorsally are long simple bristles, inferiorly bristles with an articulated terminal piece. The jaws consist superiorly of a pair of curved maxillæ and about six small dental plates on each side. The anterior edge of these in ordinary views from above is minutely denticulated. The mandibles present a crown and anterior projection. This form comes nearest the *Staurocephalus minimus* of Langerhans [1] from Madeira.

17. *On certain remarkable Structures resembling Ova from Deep Water.* *By* Professor McIntosh, *M.D., LL.D., F.R.S.*

When carrying out the work for Her Majesty's Trawling Commission, an old willow-basket came up in the net on August 15, 1884, fifteen miles S.E. of the island of May. This, besides other interesting marine forms, had attached to it certain peculiar dull, yellowish structures resembling ova, about an eighth of an inch in diameter. They adhered to each other in the form of a single layer along the bark of one of the willows. They were nearly circular, with a short, slightly curved distal appendage. The capsule was yielding, but tolerably tough, and the contents consisted of a soft and cohesive gelatinous substance of a pale colour. The minute structure was explained. No change occurred, though kept for a considerable time in the marine laboratory, until decomposition set in. Their relationships are at present unknown.

18. *On the Ova of Callionymus lyra, L. (the Skulpin).* *By* Professor McIntosh, *M.D., LL.D., F.R.S.*

So little was known about the breeding of this fish that the most recent work on British fishes, viz., that of Dr. Day, gives nothing worthy of note. At St. Andrews it was found that the ovaries were not sufficiently advanced for reliable observation in regard to the condition of the eggs till the middle of June, but that from this date till about the middle of August several favourable examples occurred. The ovaries in a well-developed female form a somewhat cordate mass, bifid in front but connate posteriorly, and, like the spermaries, covered with a silvery coating of the peritoneal lining. The ova are very minute (·028 to ·03 of an inch in diameter) and translucent, and are truly pelagic. In appearance they are characteristic. Each has a very fine hyaline *zona radiata*, furnished externally

[1] *Zeitsch. f. wiss. Zool.*, Bd. XL. p. 257.

with a series of hexagonal reticulations like those of the ruminant honeycomb stomach. When the edge of the ovum is examined, the septa bounding the reticulations stand out prominently, and in sections made by Mr. Prince these would appear to be modifications of the outer surface of the *zona radiata*. In some views the free edges of these reticulations are minutely crenate. The yolk, as in many other pelagic ova, is transparent.

So far as observed, a considerable number of ova—proportionately to the size of the ovaries—seem to arrive at maturity simultaneously.

This ground-loving fish has therefore truly pelagic eggs; but, unfortunately, this season the sexes were not simultaneously procured in a condition to carry out the development.

---

19. *On the Zoocytium or Gelatinous Matrix of* Ophrydium versatile. *By* Professor ALLEN HARKER, *F.L.S.*

Unusual opportunities of obtaining the colonies of *Ophrydium versatile* in very large quantities during the past summer have led to my devoting some time to the study of the gelatinous matrix, in or upon which the infusorium is found. I have got as much as a quart measure full of the colonies in a few minutes in our canal. The apparently spheroidal mass is not solid, but forms an irregular hollow spheroid, and in or upon the outer surface the individual *Ophrydia* are situated at regular distances from each other. The colony is at first found attached to the submerged stems of *Myriophyllum* and *Anacharis*, at as much as two or three feet below the surface, the hollow usually containing a large bubble of gas. After a while the colony detaches itself and rises to the surface, and floats about for some days. The infusoria then leave the zoocytium, which continues to float about, attracting a miscellaneous collection of diatoms and other algæ, infusoria, worms, and arthropodous larvæ, becoming a perfect menagerie of living beings.

In perfectly fresh slices of the colony, under a power of 300 diameters and upwards, a large number of unbranched threads, regularly divided by septa, are invariably to be found, and on one occasion I found one of these threads in active motion, suggesting a filamentous alga allied to *oscillatoria*. The dried gelatinous substance has by many botanists been described as a plant, and Suhr described it as *Coccochloris pila*; but Rabenhorst excludes it, and adds, 'Specimina omnia quæ vidi in algis meis Europæis sic et duo in herbario Suhriano pertinent ad Ophrydium versatile' (*animalculum!*).

Wrzesniowski, in his paper on *Ophrydium* in the 'Zeitschrift für Wissenschaftl. Zoologie,' 1877, figures and describes the long dichotomously branching thread-like pedicle of the animals, and this is recognisable in suitably mounted slices under $\frac{1}{4}$ obj., but, so far as has been observed, the threads I describe do not appear to be similar. It is just possible they may be accidental visitors in the colony, though they very closely resemble specimens of *Aphanothece stagnalis* which I have examined, this being an Alga with a dense gelatinous exudation.

The gelatinous mass associated with *Ophrydium* is of a very obstinate character, and resists the action of almost any reagents but strong sulphuric acid.

After boiling in distilled water for half an hour the gelatinous character is almost unaltered, and only after prolonged boiling in weak potassium hydroxide could the solution of the jelly be obtained. After some hours' boiling, and subsequent treatment with weak acetic acid to get rid of the carbonate of lime (whole minute crystals are distributed throughout the mass), the residue, a flocculent mass, is found to consist entirely of the threads before mentioned. These do not change colour on the addition of strong nitric acid; nor, again, do they give satisfactorily the celluloid reaction with iodine and sulphuric acid. Their nature remains an open question. The author adds some further notes on the animal. When light is allowed to fall only on a part of the colony, all the animals in a very short time congregate to that part of the zoocytium, and on the whole being freely exposed again to light they partially spread themselves over the surface, though a majority leave the matrix altogether. In tanks they showed no disposition to form new colonies as described by Savile Kent, but collected in masses

at the bottom. A sufficient quantity was thus obtained to extract the colouring matter by alcohol in suitable quantities for examination, the result being the separation out of chlorophyll with smaller quantities of xanthophyll, as the author has done in the case of Euglena.

Supplementary Meeting.—PHYSIOLOGY.

1. *On the Action of Atropine on the Secretion of the Kidney; its Evidence as to the Mechanism of the Secretion.* By J. McGregor-Robertson, *M.A., M.B.*

The author stated that he employed atropine because of an idea that its action might aid in distinguishing between different parts of the process of secretion in the kidney.

Assuming the filtration theory regarding the nature of the process in the glomerular tufts, and having regard to the elaborate researches of Wilibald Schmidt of Voigtland on filtration, the author did not see any good reason for asserting that albumen did not filter through the glomerular walls into the tubules. If albumen was filtered through, what became of it, was the question. It was a reasonable view that it might be reabsorbed by the renal epithelium. In connection with this view, the author was struck with the statement that atropine had no such effect on the urinary secretion as it had on the salivary secretion. It was known that atropine abolished the salivary secretion by paralysing the salivary cells, and that it abolished the secretion of sweat, probably by a similar action. If atropine acted at all on the secretion of the kidney, it might be supposed to act in a similar way by paralysing the renal cells. If the view that these cells reabsorbed the albumen were correct, paralysis would cause the appearance of albumen in the urine. It was these considerations that led the author to undertake the experiments. The experiments had not as yet answered the question regarding albumen. The results obtained, following the injection of atropine, were:—

1. A fall in the production of water, and
2. A rise in the production of urea.

At a later stage, when the animal was recovering from the effects of the drug, there were:—

1. A rise in the production of water:
2. A fall in the production of urea, and there was also a suspicion of albumen, but on this last the author did not wish, at the present stage of the inquiry, to lay stress.

The experiments seemed to show clearly that the process by which water was separated was different from the process by which urea was separated, since invariably the quantity of the former fell when that of the latter rose.

The author did not wish to commit himself to any theoretical explanation, but he pointed out that, accepting Heidenhain's view regarding the separation of urea by the renal cells, the atropine might stimulate the cells, thus causing increased separation of urea and increased absorption of water, and that some degree of exhaustion following the stimulation would account for the fall in the separation of urea and the rise in the quantity of water, less of it being reabsorbed by the partially exhausted cells.

---

2. *On a Chemical Difference between Living and Dead Protoplasm.* By Oscar Loew, *Ph.D.*

It has been long since a question why the manifold chemical changes going on in a living cell of a plant or an animal suddenly cease with the death of the cell. None of the hypotheses offered proved to be satisfactory. The living cell is

undoubtedly full of a wonderful chemical energy, and the most complicated syntheses are performed with ease. Think of a bacterium, that lives and multiplies in acetate of ammonia solution, and forms its albumen, fat, and cellulose from this compound of so simple a composition! Think of the continued production of protoplasm that goes hand in hand with the perpetual destruction by respiration, and certainly a most energetic chemical activity becomes evident.

In 1875 the first attempt was made to trace this energy back to a peculiar chemical constitution of the albumen that composes the protoplasm. The physiologist E. Pflüger, in Bonn, was the author of this hypothesis. He believed the albumen to contain cyanogen groups, which take up the elements of water, and thus the albumen would lose the agility of the atoms and change into another substance of less chemical energy—the dead albumen.

This hypothesis hardly found the recognition it deserved. It was only Detmer, Professor of Botany in Jena, who in 1880 accepted and defended similar views. In his opinion the chemical change of the albumen takes place by atomic displacement, and while in the living albumen a most energetic motion of the atoms leads to a continual dissociation, this ceases entirely in the dead or ordinary albumen. Neither Detmer nor Pflüger made any experiments whatever.

It was in 1881 when, starting from my own hypothesis of the formation of albumen in plants, I was led to the conclusion that the albumen of the living protoplasm contains aldehyd groups which are lost in the albumen of the dead protoplasm by atomic displacement. I therefore concluded that these easily changeable and energetic aldehyd groups could be demonstrated by the action upon an alkaline silver solution. Living cells should give a reduction of the silver solution, dead cells should not. The first experiment succeeded. It was made with an alga named Spirogyra. The slides were exhibited, which under the microscope demonstrate this difference very clearly, the protoplasm is perfectly black in one case, and not at all in the other case, where dead cells (killed by a temperature of 50°, or by an acid) had been submitted to the silver reagent. This silver reagent shows still action in a dilution of 1 part of silver to 200,000 parts of water. Not all objects show this reaction. Objects in which the killing process is performed too quickly cannot give the reaction, the silver solution itself being poisonous. There can also exist many obstacles that prevent the reaction, as presence of chloride of sodium, existence of an impenetrable membrane, &c. The phenomenon known as argyria is probably also founded upon the reaction of the active albumen of living protoplasm. In this case the metallic silver is deposited in different organs of the human body, when treated internally by nitrate of silver.

The kidneys of frogs and caterpillars show also the reaction, young hairs of plants, parts of leaves, roots, and the cells in living wood. Diatoms and infusoria die altogether too quickly to give the reaction; also some algæ of the higher classes behave likewise, and parts of most of the animals.

Many experiments were made to prove that this reaction is caused solely by the character of the *albumen* of the living protoplasm. It will suffice here to mention that I have *shown by analysis* that the oxygen of the reduced silver oxide has really entered into the molecule of the albumen.

The supposition that the reducing atomic groups in the active albumen are nothing but aldehyd groups receives a strong support by the fact that *hydroxylamine* proves to be a poison of the most general character. We know that this substance acts upon all aldehyds with great readiness, even in a very diluted and perfectly neutral solution. Its poisonous qualities can find no other explanation than that it acts upon the aldehyd groups in the living protoplasm, causing disturbances that lead to disorganisation in the cells.

While these experiments prove that the albumen of the living cell is quite a different substance from that of a dead cell, and thus a foundation for an explanation of the great chemical activity of the living cell is furnished, still I am at the same time far from believing that hereby all vital action can be explained. The cause for the divisions of cells, the nervous activity, the growth after prescribed rules, the wonderful differentiation of the various functions of a living body,

the mechanical actions, the construction itself of the protoplasm, that appears as a wonderful machinery built up with molecules of active albumen—all this appears as mysterious as heretofore.

[For details see 'Die Chemische Kraftquelle im Lebenden Protoplasma.' I. A. Finsterlin: Munich, 1882.]

---

3. *A Comparative View of the Albuminous Substances contained in the Blood of Vertebrate and Invertebrate Animals.* By W. D. Halliburton, *M.D., B.Sc., M.R.C.P.*

Introduction. General remarks on proteids; the division of blood into corpuscles and blood plasma. Lymph and hæmolymph.

A. The proteids contained in the corpuscles. Hæmoglobin.

B. The proteids contained in the plasma. This comprised the greater part of the paper.

1. The globulins; fibrinogen, paraglobulin, hæmoglobin, hæmocyanin.
2. The albumens. The varieties of serum albumen.

The differences between these two classes of proteids, and the methods of separating them employed from the time of Denis to the present day.

The part each plays in the formation of fibrin. The differences noted in these bodies in various classes of vertebrate and invertebrate animals. In considering the vertebrata, special stress will be laid on the differences observed in the serum albumen of warm and cold blooded animals.

Among invertebrata the class of Crustacea will be most fully considered. Hæmocyanin, its composition, properties, distribution, and function. The clot in invertebrata—is it a mere coalescence of cells or plasmodium, or is it due to the formation of fibrin as in vertebrates? Experiments in support of the latter view were quoted.

---

4. *On the Striated Muscles in the Gills of Fishes.* By Dr. J. A. McWilliam.

There is present in the gills of fishes a comparatively large amount of muscular substance, and this substance assumes a somewhat unexpected form—that of transversely-striated muscle instead of the non-striated tissue which one might be more ready to expect in such a situation. Striated muscle exists in the gills of all the fishes I have examined—both in Elasmobranchs and in Teleostean fishes, though the relations of the muscular structures are not identical in these two orders. There are two situations in which muscle exists in the gill.

In both Elasmobranchs and Teleosteans a band of muscle entering the branchial arch at its dorsal attachment passes along the arch more or less parallel to its long axis and lying towards its pharyngeal aspect. As this muscular band approaches the ventral extremity of the arch, it thins off and ends. Muscular tissue exists in another situation in the gills—between the two rows of filaments borne by each branchial arch. The inner borders of these filaments are united to one another in Teleosteans by a considerable amount of connective tissue, and in this tissue lies an extensive series of muscular bundles. The muscular fibres arise from the cartilage of the branchial arch or from the surrounding connective tissue, and pass outwards between the branchial filaments to end in a slender tendon which is inserted into the point of junction of the sheaths of the two adjacent filaments.

In the skate the muscular bundles arising from the branchial cartilage are not inserted as in the Teleosteans, *e.g.*, salmon and eel, but pass outwards in the partitions which separate the branchial compartments, and finally become continuous with the muscular tissue lying beneath the integument which lines the exterior of the branchial chamber.

The gill-muscles are innervated by the vagus. Stimulation of the vagus nerve causes contraction of the muscles referred to; this leads to a movement of each gill as a whole, and also an erecting movement of the gill filaments in Teleosteans at least.

A reflex contraction of these muscles can readily be induced by stimulation of various parts, *e.g.*, the spinal cord.

5. *On the Structure of the Intestine in the Hedgehog and the Mole. By* Dr. J. A. McWilliam.

The intestine of the hedgehog, like that of certain other mammals, shows externally no division into a small and large intestine.

I have found that there exists, however, a histological division into parts corresponding to the small and large intestine of man.

In the upper and longer portion of the hedgehog's intestine—that corresponding to the human small intestine—the details of structure are for the most part similar to that of man, with the exception, as one might expect, of valvulæ conniventes. The villi are large and densely set. In vertical sections they show with remarkable clearness the lacteal vessels which they contain. These vessels form a rich plexus instead of a simple loop or a blind tube as in man; they approach the surface of the villus and lie in close relation with the basement membrane, instead of being confined to the median part of the villus and enclosed by a considerable amount of adenoid tissue as in the human villus.

The lower portion of the hedgehog's intestine—that corresponding to the large intestine of man—resembles in the chief points of its structure the human colon. The longitudinal muscular tissue, however, is uniformly arranged around the bowel instead of being collected into three bands.

The transition from the villous part of the hedgehog's intestine to the non-villous part is abrupt, just as is the transition from the characteristic structure of the small intestine to that of the large intestine in man.

The intestine of the mole presents some remarkable features. One of the most striking of these is the entire absence of villi. The mucous surface of the bowel along the greater part of its length is beset with ridges, which are elevations of the mucous membrane projecting into the interior of the intestine. At the lower part of the bowel there are no ridges; this part corresponds to the large intestine of man. The ridged part, on the other hand, corresponds to the small intestine of man. The transition from the ridged to the non-ridged part is comparatively sudden.

The arrangement of the ridges is strikingly different in the upper and lower portions of the ridged part of the mole's intestine. In the upper part the ridges are so arranged as to form a pretty close network with polygonal meshes of various sizes on the internal surface of the bowel. In the lower portion of the ridged part of the intestine the ridges are, on the other hand, arranged longitudinally; they run in the long axis of the bowel, pursuing a remarkable wavy course and maintaining a well-marked parallelism to each other. The transition from this arrangement to that in the upper part of the intestine is very gradual.

The portion of bowel which shows the network of ridges alluded to probably corresponds to a duodenum and jejunum, while the longitudinally ridged part is probably equivalent to an ileum.

Vertical sections show that the structure of the ridges is essentially similar to that of the hedgehog's villi. The lacteals are similarly arranged, and are seen with remarkable plainness without the application of any process of silver nitrate staining or of injecting the lacteal vessels.

The peculiar ridges of the mole's intestine may possibly have some relation to the ridges which are described by Meckel as occurring in the human intestine at a very early stage of development.

6. *On Plant-Digestion, especially as occurring in* Carica papaya. *By* Sidney Martin, *M.D., B.Sc., M.R.C.P.*

1. History of the discovery of proteolytic ferments in the vegetable kingdom—in the 'insectivorous' plants, and in the seeds.

The two different uses of the ferments—(*a*) for the assimilation of nitrogenous

material, and (*b*) for the metabolism of the reserve-proteid. This second use will be chiefly considered.

2. The uncertain state of knowledge of the character of vegetable proteids, with a *résumé* of the latest researches.

Proteids in the juice of the fruit of *Carica papaya*. Action of the proteolytic ferment, papaïn, on animal albumen and on the proteids occurring in the juices.

Discussion of the metabolic changes, especially as regards formation and fate of peptones and crystalline nitrogenous products. Indications for future researches.[1]

9. *The Preservation and Prolongation of Life to* 100 *years.* *By* PROTHEROE SMITH, *M.D.*[2]

The accuracy and precision which mark the rapid motion of the steam-engine, continuing its ceaseless work apparently without deterioration, afford a type of what has been often observed in regard to the life of man. If the parts, or organs, on the normal condition of which the existence and continuance of our being mainly depends, in the same way, are kept in their place, and free from the friction of counteracting circumstances, the living human machine will also be found to possess macrobiotic powers far beyond what is commonly supposed. The popular objection to this statement consisting of the idea that the limit of natural life is four score years and ten, is proved to be a misconception of the authority on which this assumption relies. Senile decrepitude, leading to premature decay, is shown usually to result from derangement of those mechanical forces which in health sustain the body and its essential vital organs. But when restored, the 'mens sana in corpore sano' will not only be often reinstated, but life also greatly extended so as to warrant the answer in the affirmative to the question, 'Can we attain to the age of a hundred years, and live happily so long and even longer?' In naming certain organs and their functions as essential to healthy life, it will be seen how often they become deranged and interrupted in their action by the altered form of the bony structure of the body, resulting from advanced age or disease. This alteration in the bony structure is a gradual loss of the normal curvature of the spine, causing the back to become ultimately *convex* instead of *concave*, as in its natural sigmoid form, thus throwing forward the head and shoulders into a stooping attitude, and displacing the pelvis towards a *horizontal* plane instead of its natural *inclined* position. This alteration causes a compression and displacement of the various important organs of the body, which impede their action, and result in the gradually progressive deterioration of both the bodily and mental powers in senile decrepitude. The stooping position of the body causes a continued strain upon the muscles of the back in order to support the unnatural overhanging weight in front, consequent on the loss of the natural balance of the body. The disturbing cause of this change is directly attacked, and gradually removed by a simple mechanical appliance, which restores the spine to its natural form and the upright position of the body, and brings the pelvis back to its natural inclined position. For this purpose the 'Pelvic Band' has now been used successfully by the author for many years, effecting this object by a gentle spring action, exerting a continuous pressure *forwards* upon the spine in the hollow of the back, and *backwards* upon the pelvis and shoulders in front. The result thus effected has been in several

[1] For details of results, see *Journal of Physiology*, vol. v.
[2] Published *in extenso* by John Avery & Co., Gallowgate, Aberdeen.

hundred cases a complete restoration of the natural upright position and sigmoid form of the body, accompanied by the recovery of good health with the enjoyment of prolonged life.

Supplementary Meeting.—BOTANY.

1. *On the Application of the Anatomical Method to the Determination of the Materials of the Linnean and other Herbaria. By* Professor L. Radlkofer.

As I have set forth in a speech on the anatomical method, delivered before the Munich Academy in 1883, a real furtherance of systematic botany may be looked for from the employment of anatomical and histological characters.

It is to this application that I have given the designation *Anatomical Method*, and I have exerted myself for years to bring it to bear on systematic botany.

For my own part, I have sought to rely upon anatomical characters in my labours on the Sapindaceæ, and I may venture to say successfully, especially as far as the genus Serjania is concerned, by making use of the anomalous structure of the wood of these tropical climbers in defining the species. On this subject I had an opportunity of addressing this Association at Norwich in 1868; therefore I will not enlarge upon it now.

After having thus initiated the anatomical method and found my expectations therefrom fulfilled, I endeavoured to apply it to other families, such as the Acanthaceæ, the Sapotaceæ, the Capparideæ, &c., as more fully detailed in the beforementioned speech.

Other botanists, I am gratified to see, have followed me in this direction, particularly some of my pupils at the University of Munich, some of whom, like Dr. Hobein, I have induced to investigate isolated families in relation to their anatomical peculiarities; others, Dr. Bokorny and Dr. Blenk for example, to trace certain anatomical characters found in several families all through these families, in order to determine the constancy and systematic value of such characters for each of these families.

By means of the results thus obtained, and to be obtained, I think it is now possible, without very great difficulties, to clear up the doubts respecting the fragmentary materials of the important older Herbaria.

In the first place comes the Linnean Herbarium and the Herbarium of the Hortus Cliffortianus, formed by Linneus, and then the Herbaria of Linneus's predecessors, Plukenet, Sloane, Paul Hermann, &c., upon whose plants Linneus founded the majority of his species.

Thanks to the care of English botanists and English learned societies, these Herbaria, so important for the correct interpretation of Linnean species, have been faithfully preserved intact for a hundred years and more, up to the present day.

And now at the present day is possible what formerly was impossible, namely an exhaustive review of the contents of these Herbaria with references to the writings of their former possessors—now, with the aid of the anatomical method, this might be attempted, and should in my opinion be attempted without further delay. These Herbaria should henceforth not merely be preserved; they should, by the diffusion of a new light on their contents, become useful to everyone in a scientific sense, even to those who are unable to look through them.

As far as the Linnean Herbarium is concerned, Sir Edward Smith in his day endeavoured to extract therefrom a correct conception of the Linnean species; but the slender scientific means of his time enabled him to arrive at the goal in only a few instances. Nevertheless, his contributions to Rees's 'Cyclopædia' on this subject are of great value, and deserve republication in a collective form, in order to make them generally available, as I suggested in the speech alluded to at the beginning.

The work begun by him should now with the help of the anatomical method be resumed and completed.

Perhaps I may be permitted to call to mind an instance in which the sole way of arriving at any certainty regarding the materials in old Herbaria mentioned was by employing the anatomical method. I mean with regard to what is to be understood by *Paullinia curassavica* L. and *Paullinia polyphylla* L., which we now refer to *Serjania*. The same was the case with other species of these diversified and difficult genera, the members of which, in the absence of fruit, often cannot be referred to the right genus, even by one well acquainted with them, except calling in the aid of the anatomical method. And what holds good for these genera holds good for numerous others.

To mention only one more plant, *Sideroxylon mite* L., which I have only been able to thoroughly elucidate within the last few days on having recourse to the Linnean Herbarium; perhaps I may be permitted to explain how the anatomical method alone led to its elucidation.

Sprengel, perceiving that certain of the characters attributed to this plant by Linneus did not accord well with the genus Sideroxylon, regarded it as a species of Myrsine and named it *Myrsine mitis*. Under this name, too, it was found by Dr. Bokorny in the Munich Herbarium, and by him recognised as an exception in respect of a prominent anatomical character denoting the Myrsineæ, being destitute of the internal resin-glands which give the dotted appearance to the leaves. A second similar exception was offered by *Myrsine marginata* Hook.[1] Later investigations on the systematic value of the structure of the wood in various families, carried out by another pupil of mine, Mr. Solereder, led to the supposition that the two plants in question did not belong to the Myrsineæ at all.

With regard to *Myrsine marginata*, fragments of the original plant of which I was able to examine through the kindness of Professor Oliver, an anatomical investigation soon brought to light that it had been wrongly placed, really belonging to the Sapotaceæ rather than the Myrsineæ, and henceforth to be designated *Chrysophyllum marginatum*.

And as to the *Myrsine mitis* Spreng., that turned out to be a species of Ilex, the South African *Ilex capensis* Sond. Unfortunately this result gave no clue to the identity of *Sideroxylon mite* L., and this appeared permanently hopeless; for, on making inquiries, I was informed that it did not exist in the Linnean Herbarium. But after my arrival in England, as I was able to look for it myself, it was easy for the eye sharpened by the anatomical method to detect it, in spite of the absence of flowers and fruits, and to decide that it was nothing else than *Ilex capensis* Sond., which now, according to De Candolle's rules of nomenclature, must be called *Ilex mitis*.

It would seem superfluous to cite other examples in order to demonstrate the value of anatomical characters in systematic botany, and how much science would benefit from a sifting of the older herbaria by the aid of the anatomical method.

Permit me, therefore, to conclude with an appeal to all English botanists to direct their attention and their influence to the accomplishment of the work which I have suggested; in doing which the British Association might perhaps contribute substantial assistance. The thanks of botanists of all times would certainly accrue to England therefrom.

---

2. *On the Influence of Impregnation on a Plant.* *By* E. J. Lowe, *F.R.S.*

Some experiments were made in 1884 and continued in 1885 in order to ascertain to what extent a plant was influenced by the impregnation of a flower (*i.e.*, as to whether the effect of impregnation was confined to the solitary individual flower or extended along the branch which produced the flower).

A self yellow mimulus, M. LUTEUS *Willd.* was selected for the experiment, and this was crossed with pollen from a copiously spotted mimulus known as

[1] See Bokorny in *Flora* 1882, pp. 374–376.

M. CASHMERIANUS *of Gardens.* The latter being dwarf in habit, bearing somewhat large, and exceedingly brilliant flowers. Both parents are quite hardy and herbaceous.

Two specimens of *M. luteus* were placed in a greenhouse where there were no other mimuli. When the flower buds were almost ready to burst open, a portion of the flower was cut away in order to get at the pistil, and in this manner three blooms were impregnated with pollen from the *M. Cashmerianus,* and the small flower buds above them were not allowed to bloom.

The second plant was treated in the same manner, but was crossed with pollen from another plant of *M. luteus.*

When the seed pods were nearly matured, three more buds on the same stem (and obviously above those formerly crossed) were allowed to mature, and when nearly ready to expand were cut open and impregnated *in both plants* by pollen from another plant of *M. luteus.* These experiments were therefore :—

1. A self yellow mimulus crossed with a spotted mimulus.
2. A self yellow mimulus crossed with a yellow mimulus.
3. The yellow mimulus (experiment one) again crossed with a yellow mimulus.
4. The yellow mimulus (experiment two) again crossed with a yellow mimulus.

More than a hundred seedlings resulted and bloomed, and *every one of them* were spotted.

There was no difference in the seedlings in experiments two and four, every plant being a copy of *M. luteus,* the two parents.

In experiments one and three, every seedling was spotted and having characters intermediate between the two parents (a yellow flower and a spotted flower). Six, however, had the spots on a white ground, whilst in the remainder the ground colour varied in different shades of yellow. There was not a single plant with a self yellow flower, and there was no difference in the appearance of the flowers in experiments one and three.

These experiments have been repeated with the same results, and the plants are now in flower.

Thus the impregnation of the first flowers was communicated through the flowering branch to the buds forming higher up the stem, and produced seedlings identical with those from the former impregnation, and the second impregnation with a yellow flower was unable to alter the offspring.

It may be mentioned that these experiments disclosed the fact that the two lips of the pistil of the mimulus are exceedingly sensitive, closing rapidly when touched by the brush, either *with* or *without* pollen. Every species of mimulus that has been examined showed this sensitiveness.

From the above cross has resulted a most beautiful strain of hardy mimuli.

---

3. *On the Impregnation of Composite Flowers.* *By* E. J. LOWE, *F.R.S.*

A large number of experiments have been made during the last three years on the impregnation of the single dahlias, the result of which may be briefly stated.

If a bloom of the single dahlia be examined it will be found that the marginal portion of the flower-head is in a condition to be impregnated before the centre of the same flower-head, so that in order to impregnate every portion of the flower-head, it is requisite to continue the operation for several days.

Taking advantage of this circumstance, an individual *flower-head* was impregnated three several times with different pollen, so that three distinct breeds of flowers were obtained from one flower-head.

In one example the outer rim was impregnated with clematis-like flowers, the next rim with flowers having a coloured centre, whilst the centre was crossed with flowers having a star-like character, the petals revolved and giving a wheel-like appearance.

In saving the seeds from a ripe seed pod, those along the outer edge were kept

separate from those within this edge, and from those in the centre of the pod. (The shape of the seeds alters from the margin to the centre, but the plants resulting from those on the margin and the centre, if impregnated alike, do not vary).

Thus in composite flowers every individual flower can be made to produce distinct variations on the same flower-head.

An experiment was tried as to whether it required more than one pollen grain to impregnate a flower. A white-flowered dahlia was selected as the seed-bearer, and this was crossed with pollen from a deep red flower. When simply crossed this produced plants having blooms from pink to red, and three plants with white flowers, whilst if crossed with pollen containing four times as many grains from a white flower as from a red one, the result was in 172 seedlings, 79 were pure white, and all the others pale in colour, none being nearly as dark as the red flower from which the pollen had been taken.

The plan adopted to obtain certain proportions of pollen grains was after consideration as follow:—

Four brushes were filled with pollen from a white dahlia, and one brush from a red dahlia, and this was collected from these five brushes on to a larger brush, and this larger brush was the one used to impregnate the example selected.

It is easy to get an approximate idea of the colours to be obtained by certain crosses by the mixture of moist paints or dry powders, and in the case above mentioned, the mixture of four times as much white as red was singularly borne out, as no seedling produced flowers darker than this mixture. Those who are practically aware of the difficulty of raising white seedlings even from the seeds of a white dahlia will understand the success of these experiments, and will be convinced that a number of pollen grains are necessary in order to effect impregnation, or at all events have the power of acting together.

---

4. *On the Occurrence of Fungi in the Roots of Orchids.* By J. MACMILLAN.

It has long been known that the mycelia of fungi occur in the roots of orchids. Prillieux[1] saw them in *Neottia Nidus avis,* Reinke[2]. notices their occurrence in Corallorhiza and Epipogon, and several other writers have noticed them. De Bary, in a lecture on symbiosis given at Innsbruck in 1879, also mentions the fact.

As yet no systematic study of the phenomenon has been made. The difficulties attending such study are great. I propose here to record the results of my examination of several species of orchids, chiefly epiphytal orchids.

Epiphytes.

Cattleya Gaskelliana. Plant in full flower, few aerial roots, no trace of mycelia in aerial roots one year old, no trace in fresh shoots of this year.

C. Mendelii. Plant not in flower, in one aerial root mycelia found.

C. Mossiæ. Plant examined three months after flowering, many aerial roots containing mycelia. One root coming from a pseudobulb pushing out a flower contained abundant mycelia.

Oncidium Forbesi. Plant in full flower; no trace in any part of any aerial root.

O. Forbesi. Another plant not in flower; no trace in any aerial root.

O. crispum. Plant not in flower, no trace of mycelia.

O. Krameri. Plant not in flower, no trace of mycelia.

O. fuscatum. Plant not in flower, no trace of mycelia.

Stanhopea grandiflora. Plant in full flower, perfume of flower very powerful, aerial roots abundant and mycelia in these abundant.

S. oculata. Plant examined one year after flowering, many withered aerial roots in which no trace, many new aerial roots with mycelia abundant.

Odontoglossum triumphans. Plant not in flower, numerous pseudobulbs and aerial roots springing from them. No trace of mycelia.

[1] *Annales des Sciences Naturelles,* 1856.

[2] *Flora,* p. 145, 1873.

O. Alexandræ. Plant in flower, no aerial roots on plant.

O. hystrix. Plant with many pseudobulbs, few aerial roots, has not flowered for more than two years, no trace of mycelia.

O. Rossii majus. Plant with many pseudobulbs, few aerial roots; examined five months after end of flowering period, which extended over ten weeks. No trace of mycelia.

O. vexillarium. Leafy plant with pseudobulbs, few aerial roots; examined three weeks before flowering. No trace of mycelia.

O. cariniferum. Plant similar to last, will flower in spring. No trace of mycelia.

Dendrobium nobile. Plant in flower, many old and a few new aerial roots. No trace of mycelia.

D. Cambridgeanum (Cantabrigense?). Many old and few new aerial roots, no trace of mycelia. Plant not in flower.

D. Farmerii. Plant not in flower, several vigorous aerial roots. No trace of mycelia.

D. tortile roseum. Plant like preceding, similar results.

D. Falconerii. Plant examined three months after flowering, many aerial roots old and new, no trace of mycelia.

D. crassinode Barberiana. Plant not in flower, few roots. No trace.

D. primulinum giganteum. Plant strong and vigorous, few aerial roots; no trace of mycelia.

D. bigibbum. Plant has not flowered for two years, has been kept dry, a few new aerial roots springing from apparently withered stems. No trace.

D. formosum giganteum. Plant with few aerial roots. No trace.

D. aggregatum majus. No trace of mycelia one month after period of flowering.

Aerides odoratum. Strong, healthy plant with many large aerial roots. No trace of mycelia.

A. virens. No trace one month after flowering.

A. Lobbii. Examined two months before period of flowering, many thick vigorous roots. No trace.

Saccolabium ampullaceum. Plant with long, thick healthy aerial roots, examined three months after flowering. No trace of mycelia.

S. Blumei. Similar in growth to last. No trace.

S. guttatum. No trace three months before period of flowering.

Cypripedium Laurentium. Plant with thick aerial roots, examined one month after flowering. No trace.

Ada aurantiaca. Examined four months after flowering. No trace of mycelia.

Angræcum caudatum. Plant with long, thick, fleshy aerial roots, examined just before flowering; no trace.

Cypripedium Veitchi. Plant in flower; no trace.

C. Drewi. Plant in flower; no trace.

Helcia sanguinolenta. Plant not in flower. No trace of mycelia.

Dendrobium filiforme. Plant in full flower, few aerial roots. No trace of mycelia.

Cattleya Laurenceiana. Plant strong and vigorous, mycelia abundant in aerial roots.

C. trienne. Like last, very strong development of mycelia.

Terrestrial Orchid.

Disa grandiflora. Plant large, healthy, in full flower. No trace in any underground roots. No aerial roots.

The evidence afforded by these epiphytic orchids as to the nature and function of the fungi growing in them is of a somewhat conflicting character. Before discussing that evidence it will be necessary to glance at the structure of an aerial root.

At the growing apex of each aerial root is a glaucous bright green portion

varying in length in the different species. Above this, receding from the growing apex the epidermis is of a white colour.

A horizontal section shows the aerial root to consist of three concentric rings of tissue.

The *outer* or *velamen* consists of a varying number of layers of cells. In Oncidium about ten, in Aerides two or three. These cells are polygonal, closely packed together, contain no chlorophyll, many are filled with air. These give the velamen its white colour and render it hygroscopic. Through these layers of the velamen many spiral vessels are found.

The middle ring is bounded by two layers of compact cells, the outer endoderm and the inner endoderm. The outer endoderm consists of a row of thick-walled compact cells. In this row at intervals are thin-walled cells leading from the velamen to the central ring. The cells between the outer and the inner endoderm are large with chlorophyll granules, and contain the usual cell contents. The number of layers of these cells varies. I have found most in Aerides, fewest in Dendrobium. The central ring very clearly marked off from the middle ring is composed of a dense mass of fibro-vascular tissue. Next the inner endoderm the xylem and the phloem portions alternate. The thick-walled cells of the inner endoderm lie opposite the phloem portion, and the thin-walled cells opposite the xylem portion. These gradually merge into the large cells of the medulla. They do not play any important part in the investigation.

In which of these rings are the mycelia found? In all the species I have examined they occur invariably in the middle ring. Only in the cells with chlorophyll have I found mycelia; where the mycelia are most abundant the protoplasm of the cells is least. These cells are comparatively empty. Of the various rows of cells in the middle ring or zone the central contain most mycelia. I have never seen a single thread attempt to pass by means of the thin-walled cells of the inner endoderm to the central zone. Nor have I ever seen these threads in the act of penetrating the thin-walled cells of the outer endoderm. In some species of Cattleya, *e.g. Cattleya Laurenceiana*, where the development of mycelia was very strong—the central zone being nearly filled by them—I have never found them penetrating these thin-walled stoma-like cells.

The mycelia are never found in the green terminal growing apex of the root, but are first found just where the velamen with its hygroscopic cells begins. I have traced them from this point all through the aerial root as far as the pseudobulb. This they have never entered in any plant I have examined, nor have I found any trace of mycelia in any other part of the plant—flower, gynandrium, or leaf.

Again, in cells which have little or no protoplasm, the mycelia are strongest and most abundant, while in those cells with most protoplasm, which often gathers in lumps, the mycelia are thinner and less vigorous.

Constitution of Mycelia.

In some cases the hyphæ, for such I consider that part of the fungus which branches and anastomoses, are found towards the posterior portion of the root, while the mycelium portion with few branching threads is found nearer the anterior portion of the root. In *Cattleya trienne* the branches are large, thick, and with node-like swellings like the buckle-shaped swellings on the hyphæ of Basidiomycetes. Sections of the root containing these swellings were sown in a suitable medium. From these swellings came only their mycelium-like threads. In no instance have I been so fortunate as to find any fructification, either in the root or arising from sections sown in a suitable nourishing medium. From the varied appearance of the threads, however, it may be concluded that the fungi belong to different families.

Relation of the Mycelia to Cell-wall and Cell-contents.

The appearance of the cells into which the mycelia have penetrated is not essentially changed by the presence of the fungus. Near the growing apex of the root where the mycelia are first found the cells remain unaltered, nucleus and

protoplasmic bodies are unchanged. On advancing nearer the pseudobulb the cell is often filled with the threads; nucleus, protoplasmic bodies, starch granules seem to have disappeared, and only the fungus with a small quantity of cell sap appears to be left. Such a section, however, when treated with suitable reagents, shows the nucleus among the anastomosing filaments of the fungus without loss of shape or of size.

Often the cell-sap gathers into a lump in the centre of each cell, from the edges of which cell threads run in and surround the lump.

By the application of a sugar solution the plasma is drawn off from the lump of mucilage which once more, after the removal of the solution, swells up as before. From this it is evident that the protoplasmic bodies are not destroyed by the fungus.

The thickness of the cell-wall, too, plays no unimportant part in the distribution of the mycelia. Where the walls are thick the threads have greater difficulty in penetrating, and are not so numerous and strong as in roots where the cell walls are thinner and therefore more easily penetrated.

Schultze's solution colours the cell membrane a beautiful violet colour and makes the threads disappear.

The growing thread appears with its apex at the middle of the cell wall, and where it has penetrated there is a slight swelling, both where it enters and where it emerges from the cell wall. The edge of the aperture where the threads have penetrated is quite smooth, so that it may be concluded that the membrane has been dissolved at the point of penetration.

Entrance of Mycelia into Roots.

In what way do the fungi first enter the aerial roots? I have examined plants recently imported in a shrivelled condition and have found no trace of fungi. Two years after importation still no trace; only when the plants have become established and comparatively vigorous in growth do the fungi seem to enter. That they penetrate the outer covering is evident from the following experiment. A plant of *Platanthera bifolia* was taken whose next year's tubers were ripe and already contained mycelia. These tubers were placed under a bell jar along with tubers not yet containing any trace of fungi. In four or five days these latter were infected. In their outer cells a slightly branched mycelium was found.

Again, does the orchid thrive better with or without the fungus? The evidence for and against is conflicting. I always noticed that the strongest, healthiest plants, those which produced the largest spikes of flowers, contained the most highly developed fungi.

It may be that we have here an instance of symbiosis; it may be that the fungus is imprisoned by the orchid, and made to gather nourishment for it, or afford nourishment to it, or the fungus may be a parasite pure and simple.

It is a noteworthy fact that orchids brought to this country in a dry withered condition begin to grow most vigorously when the aerial roots are entered by the fungi. On the other hand, these roots are not entered until they have attained a certain vigour. Their vigour, therefore, may be the cause of the infection, not the effect of it.

Lastly, the cultivation of these fungi has never yet resulted in the production of any fructification, so that no clue has as yet been obtained as to the genera or species of the fungus.

I hope by the examination of a much greater variety of species of foreign orchids and of our native orchis yet to throw some little light on this subject.

---

5. *Notes on Experiments as to the Formation of Starch in Plants under the influence of the Electric Light.* *By* H. MARSHALL WARD.

---

6. *On the Flora of Banffshire. By the* Rev. W. S. Bruce.

Banffshire contains over 600 species of flowering plants, besides a considerable number not considered to be truly indigenous. Of these the majority are plants of the British type, which are more or less diffused throughout the country. Very few are English, while, on the other hand, plants of the Scottish type are exceedingly abundant, such as *Pyrola media* and *minor, Trientalis europæa, Goodyera repens,* &c. Of the Atlantic type, *Scilla verna,* found at Banff and Macduff, is the sole representative, while plants of the Highland type are scattered abundantly throughout the length of the county. Many of these are found only in the higher glens and on the mountains at the south-west end of Banffshire, e.g., *Alchemilla alpina, Rubus Chamæmorus, Vaccinium uliginosum* and *V. Vitis-idæa, Saxifraga rivularis* and *S. stellaris, Luzula spicata* and *L. arcuata, Carex rigida, Epilobium alpinum,* &c. The Alpine *Alchemilla* is found along the banks of Fiddich lower down, and the *Sedum Rhodiola* and *Polygonum viviparum* grow on the sea-coast.

---

7. *On the Flora of Elgin. By* James Mackenzie.

To the west the ground is irregular, hilly, much wooded, and drained by a rivulet. The plants found are:—

Convolvulus arvensis.
Myrrhis odorata.
Datura Stramonium.
Polygonum Hydropiper.
Hypericum pulchrum.
Ulex nanus.
Pinguicula vulgaris.
Narthecium ossifragum.
Lychnis Flos-cuculi.
Radiola Millegrana.
Bromus sterilis.
Galium Mollugo.
Parietaria officinalis.
Anchusa sempervirens.
Berberis vulgaris.
Polygonum Bistorta.
Papaver somniferum.
Habenaria bifolia.
Gymnadenia conopsea.
Drosera rotundifolia.
Hydrocotyle vulgaris.
Linnæa borealis.
Mentha aquatica.
Helosciadium inundatum.

The coast from the laigh of Moray to Lossiemouth is exposed to the north and is rocky, the cliffs being of various formations.

The plants are:—

Ammophila arundinacea.
Asperugo procumbens.
Carduus tenuiflorus.
Helianthemum vulgare.
Poa maritima.
Ligusticum scoticum.

8. *On the Division and Conjugation of Spirogyra.* *By* Dr. J. M. Macfarlane, *F.R.S.E.*

9. *On a Microscopic Fungus in Fossil Wood, from Bowling.* *By* Dr. J. M. Macfarlane, *F.R.S.E.*

10. *On a new Method of preparing the Epidermal Tissues of Pitcher Plants.* *By* Dr. J. M. Macfarlane, *F.R.S.E.*

The author stated that the difficulty he had experienced in getting clean and large pieces of the epidermis from the different surfaces of pitchers induced him to try various methods of preparation. Maceration in caustic potash solution of 2 p.c. strength gave admirable results. The pitchers to be macerated were placed whole in beakers containing the solution and boiled over a Bunsen flame for from ten minutes to two hours. The pitchers of Nepenthes, if young and fresh, had both outer and inner epidermis loosened from the green cellular and fibro-vascular systems after about fifteen or twenty minutes boiling; old or dried pitchers required thirty to sixty minutes. By floating them afterwards in clean water both epidermal layers could be detached with great ease. Pitchers of Cephalotus were macerated after ten to twenty minutes treatment, but those of Sarracenia Heliamphora and Darlingtonia, except when young and tender, required boiling for about two hours, with subsequent maceration for two or three weeks in water. In this way not only could long pieces be obtained for continuous microscopic examination of the surfaces, but bottled hand specimens of the entire inner epidermis of Nepenthes could be made, showing clearly to the naked eye the *attractive, conducting,* and *secreting* surfaces, with associated glands. Bottled specimens and a series of microscopic preparations were exhibited and described, illustrating the paper. It was also pointed out that similar treatment of leaves for preparations of hairs, water and air stomata, &c., gave equally good results in many cases.

11. *On Aberdeenshire Plants as Food for Animals.* *By* William Wilson, Junr.

TUESDAY, SEPTEMBER 15.

The following Report and Papers were read:—

1. *Report on the Migration of Birds.*—See Reports, p. 685.

---

2. *Note on the Intelligence of the Dog. By* Sir JOHN LUBBOCK, *Bart., F.R.S.*

The man and the dog have lived together in more or less intimate association for many thousands of years, and yet it must be confessed that they know comparatively little of one another. That the dog is a loyal, true, and affectionate friend must be gratefully admitted; but when we come to consider the psychical nature of the animal, the limits of our knowledge are almost immediately reached. I have elsewhere suggested that this arises very much from the fact that hitherto we have tried to teach animals, rather than to learn from them: to convey our ideas to them, rather than to devise any language or code of signals by means of which they might communicate theirs to us. The former may be more important from a utilitarian point of view—though even this is questionable—but psychologically it is far less interesting. Under these circumstances, it occurred to me that some such system as that followed with deaf mutes, and especially by Dr. Howe with Laura Bridgman, might prove instructive, if adapted to the case of dogs.

I have tried this in a small way with a black poodle named Van, by taking two pieces of cardboard, about ten inches by three, and printing on one of them in large letters the word 'food,' leaving the other blank. I then placed two cards over two saucers, and in the one under the 'food' card I put a little bread and milk, which Van, after having his attention called to the card, was allowed to eat. This was repeated until, in about ten days, he began to distinguish between the two cards. I then put them on the floor, and made him bring them to me, which he did readily enough. When he brought the plain card I simply threw it back, while when he brought the 'food' card I gave him a piece of bread, and in about a month he had pretty well learned to realise the difference. I then had some other cards printed with the words 'out,' 'tea,' 'bone,' 'water,' and a certain number also with words to which I did not intend him to attach any significance, such as 'naught,' 'plain,' 'ball,' &c. He soon learnt that bringing a card was a request, and to distinguish between the plain and printed cards; it took him longer to realise the difference between words, but he gradually got to recognise several. If he were asked whether he would like to go out, he would joyfully pick up the 'out' card, choosing it from several others, and would bring it to me, or run with it in evident triumph to the door. The cards were not always put in the same places, but were varied indiscriminately, and in a great variety of positions. Nor could the dog recognise them by scent, for they were all alike, and continually handled by us. Still I did not trust to that alone, but had a number printed for each word. When, for instance, he brought a card with 'food' on it, we did not put down the identical card, but another bearing the same word; when he had brought that, a third, then a fourth, and so on. For a single meal, therefore, eighteen or twenty cards would be used, so that he evidently was not guided by scent.

No one who has seen him look down a row of cards and pick up the one he wanted, could, I think, doubt that in bringing a card he feels he is making a request, and that he can not only distinguish one card from another, but also associate the word and the object. This is, of course, only a beginning, but it is, I venture to think, suggestive, and might be carried further, though the limited wants and aspirations of the animal constitute a great difficulty.

My wife has a collie which was often in the room when Van brought the food card and was rewarded with a piece of bread, but although the collie begged in the usual manner, it never once occurred to that dog to bring a card, of which, indeed, not the slightest notice was taken.

I then prepared six cards about ten inches by three, and coloured in pairs, two yellow, two blue, and two orange. I put three of them on the floor, and holding up one of the others, endeavoured to teach Van to bring me the duplicate: that is to say, if the blue was held up, he should fetch the corresponding colour from the floor, if yellow he should fetch the yellow, and so on. When he brought the wrong card he was made to return for another till he brought the right one, when he was rewarded. The lessons generally lasted half an hour, during which he brought the right card on an average about twenty-five times. I certainly thought that he would soon have grasped what was expected of him, but although we continued the lessons for about ten weeks, at the end of the time I cannot say that Van appeared to have the least idea what was expected of him. It seemed a matter of pure accident which card he brought.

As it was just possible that Van might be colour-blind, we then repeated the experiment, substituting for the coloured cards others marked respectively I., II., and III. This we continued for another ten weeks, but entirely without success. I was rather disappointed at this; as, if it had succeeded, the plan would have opened out many interesting lines of inquiry. Still, in such a case one ought not to wish for one result more than another, as of course the object of all such experiments is merely to elicit the truth; and our result in the present case, though negative, is interesting. I do not, however, regard it as by any means conclusive, and should be glad to see it repeated. If the result proved to be the same, it would certainly imply very little power of combining even extremely simple ideas.

I then endeavoured to get some insight into the arithmetical condition of the dog's mind. On this subject I have been able to find but little in any of the standard works on the intelligence of animals. Considering, however, the very limited powers of savage men in this respect; no Australian language for instance, containing numerals even up to four; and no Australian being able to count his own fingers even on one hand—we cannot be surprised if other animals have made but little progress.

Leroy, who, though he expresses the opinion that 'the nature of the soul of animals is unimportant,' was an excellent observer, mentions a case in which a man was anxious to shoot a crow. 'To deceive this suspicious bird the plan was hit upon of sending two men to the watch-house, one of whom passed on while the other remained; but the crow counted, and kept her distance. The next day three went, and again she perceived that only two retired. In fine, it was found necessary to send five men to the watch-house to put her out in her calculation. The crow, thinking that this number of men had passed by, lost no time in returning.' From this Leroy inferred that crows could count up to four. Upon this point Mr. Howard Saunders has furnished me with the following note:—'A short-toed eagle (*Circaëtus Gallicus*), was hovering suspiciously and out of gun-shot above her nest in a large cork-tree under which I and two of my Spanish *cazadores* were standing, partially, but not carefully, concealed. One was sent away, when the eagle, after accompanying him for a short distance, returned to her post of observation. After an interval I left also, when the manœuvre was repeated, but no sooner had the bird watched me well off the ground than she unhesitatingly pitched on her nest, affording an easy shot to the third man.'

An interesting consideration rises with reference to the number of the victims allotted to each cell by the Solitary Wasps. *Ammophila* considers one large caterpillar of *Noctua segetum* enough; one species of *Eumenes* supplies its young with five victims, another ten, fifteen, and even up to twenty-four. The number appears to be constant in each species. How does the insect know when her task is fulfilled? Not by the cell being filled, for if some be removed, she does not replace them. When she has brought her complement, she considers her task accomplished, whether the victims are still there or not. How then does she know when she has made up the number twenty-four? Perhaps it will be said that each species feels some mysterious and innate tendency to provide a certain number of victims. This would under no circumstances be any explanation, but it is not in accordance with the facts.

In the genus *Eumenes* the males are much smaller than the females. Now in the

hive-bees, humble-bees, wasps, and other insects, where such a difference occurs, but where the young are directly fed, it is, of course, obvious that the quantity can be proportioned to the appetite of the grub. But in insects with the habits of *Eumenes* and *Ammophila*, the case is different, because the food is stored up once for all. Now it is evident that if a female grub was supplied with only food enough for a male, she would starve to death; while if a male grub were given enough for a female, it would have too much. No such waste, however, occurs. In some mysterious manner the mother knows whether the egg will produce a male or female grub, and apportions the quantity of food accordingly. She does not change the species or size of her prey, but if the egg is male, she supplies five; if female, ten victims. Does she count? Certainly this seems very like a commencement of arithmetic. At the same time it would be very desirable to have additional evidence how far the number is really constant.

Considering how much has been written on instinct, it seems surprising that so little attention has been directed to this part of the subject. One would fancy that there ought to be no great difficulty in determining how far an animal could count, and whether, for instance, it could realise some very simple sum, such as that two and two make four.

But when we come to consider *how* this is to be done, the problem ceases to appear so simple. We tried our dogs by putting a piece of bread before them, and preventing them from touching it until we had counted seven. To prevent ourselves from unintentionally giving any indication, we used a metronome (the instrument used for giving time when practising the pianoforte), and to make the beats more evident we attached a slender rod to the pendulum. It certainly seemed as if our dogs knew when the moment of permission had arrived; but their movement of taking the bread was scarcely so definite as to place the matter beyond a doubt. Moreover dogs are so very quick in seizing any indication given them, even unintentionally, that, on the whole, the attempt was not satisfactory to my mind.

I was the more discouraged from continuing the experiment in this manner by an account Mr. Huggins gave me of a very intelligent dog belonging to him. Cards were placed on the ground, numbered from 1 to 10; and a question being then asked: the square root of 9 or 16; or such a sum as $\frac{6+2-3}{5}$, Mr. Huggins pointed consecutively to the cards, and the dog backed when he came to the right one. Now Mr. Huggins did not *consciously* give the dog any sign, yet so quick was the dog in seizing the slightest indication, that he was able to give the correct answer. This observation seems to me of great interest in connection with the so-called 'thought-reading.' No one, I suppose, will imagine that there was in this case any 'thought-reading' in the sense in which this word is used by Mr. Bishop and others. Evidently the dog seized upon the slight indications unintentionally given by Mr. Huggins. I have brought this question before the Section in hope of inducing others with more leisure and opportunity to carry on similar observations, which I cannot but think must lead to interesting results.

---

3. *On the Development of the Food-fishes at the St. Andrews Marine Laboratory.* By Edward E. Prince.

After referring to the literature of the subject and the incomplete state of our knowledge of the embryology of the osseous fishes of British seas, the author proceeded to give details of the deposition of the ova in certain species. Of about twenty forms, deep-sea and littoral, studied in the St. Andrews Marine Laboratory, attention was specially directed, chiefly on account of their economic importance, to the six following species, viz., *Gadus merlangus*, *G. morrhua*, *G. æglefinus*, *Trigla gurnardus*, *Pleuronectes flesus*, and *P. limanda*. Amongst these species, the ova of which are pelagic, differences in the manner and duration of deposition probably obtain. Thus the extrusion of ova in the Pleuronectidæ would appear to be more rapid and continuous than in *Trigla gurnardus* and the gadoids, in which the act of spawning is, it would seem, intermittent and prolonged. The examina-

tion of the spermatozoa reveals no marked differences, except that of size, the usual enlarged head and motile filament being distinguishable in all.'

The ova treated of in this paper are extremely buoyant, and float, in the living and healthy condition, as minute transparent globes, near the surface of the water. Loss of buoyancy and transparency, as Professor McIntosh's observations[1] have shown, indicate an unhealthy or non-living state. After the germinal vesicle, readily seen in immature intra-ovarian eggs, is no longer distinguishable, the ovum consists of (*a*) a central globular deutoplasm, destitute of oil-globules in British Gadoids and flat fishes, but exhibiting in *T. gurnardus* a single, pale salmon-coloured oil-globule like that of *Brosmius americanus*, a noteworthy American Gadoid; (*b*) a cortical protoplasmic film, containing minute vesicles and granules; (*c*) a thin external hyaline capsule, separated from the vitelline mass by a narrow space, the 'breathing chamber' of Newport. The capsule is tough, structureless, slightly resilient, free from punctures or striations, and varies in thickness in different species. Thus in *P. limanda* its thickness is ·0001 in.; *P. flesus*, ·000125 in.; *G. morrhua*, ·00025 in.; and *T. gurnardus*, ·0005 in. One aperture, the micropyle, pierces the capsule, and in the species here treated of, it presents the usual simple features, being generally situated, excentrically, in the lowermost (germinal) segment of the ovum. After fertilisation, the ovum becomes clearer and more tense, and a movement of the superficial protoplasm towards the germinal pole commences. The surface of the deutoplasmic globe presents at this time a corrugated appearance, but the areas of transference were less definite than Ryder indicates.[2] The cortical protoplasm collects as a germinal disc or cap, which segments in the usual manner and performs a retrogressive movement spreading once more over the yelk, and epibolically enveloping it. Irregularity in cleavage is common, resulting in asymmetry of the disc. This feature was especially noticeable in the two reniform cells of the ovum of *T. gurnardus*, after the first cleavage, but symmetry was restored when the polycelled stages were reached. In some forms the blastodermic scutum presents a more acuminate central promontory than in others. It is acute in *G. merlangus* and *S. fario* (Oellacher), less so in *G. morrhua* and *T. vipera* (G. Brook), quite obtuse in *G. æglefinus, T. gurnardus, P. flesus, Motella mustela* (Brook), and *Perca fluviatilis* (Lereboullet). The inwardly-directed point of the scutum forms the snout of the embryo, and a thickening extends outwards (radially) which indicates the developing trunk. The cephalic swelling, the neurochord, the mesoblastic muscular plates, develop in the usual way, and between the latter the notochord is pushed up.

The differentiation of the notochord is coincident in many species with the closure of the blastopore, e.g., *G. merlangus, G. morrhua, P. flesus,* and *P. limanda*; but in *T. vipera* and *M. mustela* it precedes, while in *G. æglefinus* and *T. gurnardus* it succeeds the closure by an interval of one or two days. A like variation obtains in the time of the appearance of Kupfer's vesicle.

Several features were next referred to as probably diagnostic, and therefore worthy of note, viz., the formation of a protoplasmic reticulation upon the surface of the yelk in *P. limanda* on the eighth day; the appearance of one or more colourless enucleate stellate structures, on the yelk surface beyond the lateral margin of the embryo, in *G. merlangus* on the seventh day. This latter structure assumes the form of a 'bone-corpuscle,' and was observed in no other species studied at St. Andrews. *T. gurnardus*, previous to the act of emergence, exhibits on the yelk-surface many minute protoplasmic elevations from which pseudopodial processes protrude. Each is isolated and exhibits a nucleus and nucleoli.

Pigment appears to have a diagnostic value in the case of Teleostean embryos, though the study of a very extended series of forms can alone establish the contention that it affords a reliable means of identification. Pigment appears earliest in *P. flesus*, and as described by Professor McIntosh,[3] is 'of a peculiar pale olive-brown (brownish-yellow by transmitted light), whereas in *P. limanda* it is of a more dis-

[1] *Report of H.M.'s Trawling Commission*, 1884, pp. 31–33.

[2] *United States Fish Commissioners' Report*, 1882. 'Embryography of Osseous Fishes,' Pl. I. figs. 6 and 7.

[3] *Second Annual Report Scottish Fishery Board.* Appendix F. p. 47.

tinctive yellow colour, in fact, a rich amber shade. In the latter species the spots appear on the seventh day after deposition, and rapidly extend from the dorsum almost to the caudal termination. In neither species, however, is the yelk-surface pigmented. *G. merlangus* shows no colouration till the eighth day, when numerous pale yellow spots, having a greenish tinge, appear confined chiefly to the dorsum, but soon extending over the whole trunk, the embryonal fin and the yelk-surface. The two remaining Gadoids exhibit black pigment only. It appears in *G. morrhua* on the seventh day (in a series which emerged from the ovum on the ninth day); but in *G. æglefinus* (which emerged on the twentieth day) it was visible on the eleventh day. The spots are at first amorphous, and numerous on the dorsum; but they rapidly extend over the tail, and become densely aggregated in the mesenteric region. The 'shoulder,' above the pectoral fins is also thickly pigmented. The embryo of *T. gurnardus* exhibits scantily distributed pigment, at first of a pale sea-green tint, intermingled, two days later, with yellow corpuscles and minute black spots. This colouration also appears in the protoplasmic investment of the oil-globule present in this species.

In the development of the sense-organs, &c., no special features were observed in the species studied. The embryo remains quiescent in the lower segment of the ovum until the cardiac pulsations commence. The rhythmical movement of the heart, many days prior to the existence of a hæmal circulation, or indeed of a hæmal fluid, is an interesting physiological phenomenon, and is coincident generally or slightly subsequent to the appearance of pigment in the epiderm. It is noteworthy that the first motion of the embryonic trunk (in each series of ova studied in the St. Andrews Marine Laboratory) took place on the day preceding liberation, when the tail, now free from attachment to the yelk, is flexed and relaxed violently. These erratic movements probably assist in facilitating extrusion from the capsule. The newly-emerged embryos are extremely sensitive and delicate, and swim in a reversed position for some time. Neither mouth nor anus is developed, but branchial arches are indicated, though the clefts are incomplete. The Pleuronectidæ are even more rudimentary than the newly-hatched Gadoids, and exception must be taken to the statement of Mr. G. Brook[1] that the Gadidæ differ from all other teleosteans in the late formation of the anus. The oral aperture usually appears at the end of the first week, and one or two days later the proctodæum can be detected. The formation of large sub-epidermal spaces, especially in the cephalic region of the embryo, is a remarkable feature, the skin, as Ryder remarks,[2] 'is lifted off, perceptibly, from the underlying structures,' and the interspace formed is filled with a transparent plasma. Young embryos a week old assume a very grotesque appearance on account of this anterior enlargement. Simultaneously the epiderm becomes nodulate, the eyes are deeply pigmented, and a simple arterial and venous circulation is established. The deutoplasm continues visibly to decrease, though there is no yelk-circulation in the species here considered.

With regard to the conditions of temperature, so important in these investigations, the attempt is made in the St. Andrews Marine Laboratory to keep the water in the tanks at the same temperature as the sea outside. The laboratory is almost completely surrounded by sea-water, and by a continuous supply from St. Andrews Bay, a constant circulation is maintained through the tanks, which is highly favourable for rearing young teleosteans. It was thus possible to keep the temperature at about 40° F. during March and April, rising to 48° and 50° F. in May and June, these being the months during which the species here considered were reared and studied.

---

4. *On the Nest and Development of* Gastrosteus spinachia *at the St. Andrews Marine Laboratory.*[3] *By* Edward E. Prince.

This paper was chiefly a record of observations made upon the nidification and development of the ova of this common Teleostean in the St. Andrews Marine

[1] *Linnæan Society Journal*, vol. xviii. p. 304.
[2] *United States Fish Commissioners' Report*, 1882, p. 530.
[3] Published *in extenso* with figures in the *Ann. Nat. Hist.* for December 1885.

Laboratory. It was shown that the size of the nest depended upon the character of the materials employed and upon the number of female fishes resorting to a single nest; and it was pointed out that the dimensions (5–8 centimetres) named by Professor Möbius were often very much exceeded. If the fronds of the larger Algæ (Fuci &c.) be chosen, the nest is pear-shaped or cylindrical, and of greater capacity (length 8–10 inches, and diameter, widest part, 5–6 inches) than when more minute seaweeds (*Ceramium*, *Corallina*, &c.) are selected. In the latter case the nest is more spherical, and 3–5 inches in diameter. Compactness is secured by binding threads upon the outside, which are often so disposed as to form a reticulation, the crossing cords enclosing lozenge-shaped spaces. The substance of the cords is a secretion which exudes from the epithelial cells of the sinuous urinary canals. The cells present (as transverse sections show), at the latter end of April and during May and June, a swollen appearance. The secretion is not merely a semi-solid plasm; but, before reaching the spacious ureters at the external border of the kidney, assumes a marked funicular character. It is colourless, opalescent when freshly extruded, and of mucilaginous consistency. Möbius determined its nitrogenous composition: carmine stains it deeply, it becomes opaque in spirit, and after exposure to sea-water (for 2–3 days) it turns transparent grey or dirty white. It is thus a form of Mucin peculiarly modified, possessing extraordinary elasticity, and it is stored up in the urinary bladder. This structure is disproportionately developed, pyriform, and describes a double curve, posterior to the cervix, before debouching behind the genital pore into a urino-genital sinus forming the posterior portion of the cloacal depression, into which the anus also opens. The weaving operation as seen in the tanks of the laboratory was referred to, and the structure of the cords then described. Each cord (·0046–·0051 in. in diameter) consists of several strands (·0008–·00092 in. in diameter), and these constituent threads, again, are made up of fine homogeneous filaments adhering in parallel order. The nest is so constructed by the male as to leave numerous irregular chambers, in each of which the female deposits some ova. The ova are extremely ellipsoidal, disproportionately large, and the soft tenacious capsule assisted by an ovarian plasm causes them to adhere strongly together. If torn asunder facets or scars on the capsule mark the points of attachment to adjacent ova. The colour is a delicate pale green, which soon changes to the characteristic translucent amber tint. The hyaline capsule has a thickness of ·0013 in., and is separable into 20 to 30 lamellæ. It is minutely punctured, the pits being arranged in parallel rows. A large mass of loosely aggregated oil globules occupies the vegetative pole. Two hours after fertilisation the cap is completed at the germinal pole, and segmentation presents the usual features, though it is comparatively slow. On the fourth day the nuclei of the periblast appear, and by the eighth day the embryonal thickening is well marked, epiboly having proceeded over two-thirds of the yelk surface. At the close of the same day the mesoblastic muscular plates are well-defined. Closure of the blastopore is effected on the twelfth day, and soon after Kupfer's vesicle is distinguishable. By the seventeenth day the heart assumes the campanulate shape; and the protovertebræ are marked off from the otocystic region to the caudal plate. A hæmal circulation is visible, though languid, on the nineteenth day, and by simple lacunæ hollowed out of the yelk-cortex spacious passages are formed, and a yelk circulation, by the twentieth day, is in vigorous action. The young fish shows movement on the nineteenth day, and the first embryos emerge on the twenty-fifth day. The centrally-situated ova develop more slowly, many of these not hatching until the fortieth day. The water of the tanks varied from 41° F. in May to 50° or 51° F. early in June, and the general conditions of the laboratory being unusually favourable for the development of ova of marine fishes, the phenomena observed may be taken as almost normal.

---

5. *On the Reproduction of the Common Mussel* (*Mytilus edulis, L.*) *By* JOHN WILSON.

The common mussel is completely diœcious, and is peculiar in having the sexual elements developed in the mantle as well as in a wedge-shaped central

mass. Professor McIntosh has pointed out that the mussel reaches full reproductive maturity in April, and that there is a gradual disappearance of the ova or spermatozoa during June and July, until, in the latter month, most examples are quite empty. The female generative organs are almost invariably redder than the male, and the groups of sperm-sacs are more prominent than the ovigerous masses. When an incision is made in the fully ripe male or female organ, a creamy fluid issues, holding respectively immense numbers of spermatozoa or ova. In the ovary the ova are surrounded by a transparent hyaline investment, and, when fully ripe, the germinal area and germinal spot are lost to view, the vitellus becoming densely granular. The genital canal is readily seen, and microscopic sections show it to be clothed internally with ciliated epithelium. Natural fertilisation in all likelihood takes place in the surrounding water. Artificial fertilisation is easily accomplished. A piece of tissue containing spermatozoa is minced in a watch-glass with sea-water, and a little of the milky liquid decanted into another glass. Into the latter is then poured a little liquid containing ova procured in the same way. The glass is kept cool, and in half an hour the milkiness is removed from the liquid by repeated washings, and particles of débris sucked up by a fine pipette. Each ovum has now a considerable number of spermatozoa attached to it, and their wriggling causes it to rotate. In about four hours the clear polar or direction-cell appears. Decreasing vigour and changes of temperature cause conflicting results as to the time certain developmental stages are reached. Fertilisation so late as August 1 was partially successful. The writer's earliest attempt (and it was the most successful) was made in the beginning of June. The first segmentation takes place immediately after the appearance of the polar cell, resulting in a larger segment (macromere) and a smaller (micromere). Repeated budding of the micromere takes place, and in six or seven hours the embryo assumes its most irregular form. Thereafter it is gradually reduced to a more regular shape, and in ten hours the brownish granular contents have disappeared. In fifteen or eighteen hours the shape is almost spherical, and the contour is broken by the projecting part of what is probably the still undivided macromere. The free edge of this body is crenate. The existence of a central cavity can now be made out, the polar cell still persists in many cases, and the embryo rotates by means of minute cilia which seem to cover the greater part of its surface. Two examples (of distinct series), forty-three hours old, were characterised by having, besides the minute cilia, in the one case one strong cilium at least as long as the diameter of the embryo; in the other by two cilia somewhat longer. In both forms there were features indicating approaching differentiation of structure. Embryos have been kept alive for four days, but not in a healthy condition.

The very youngest forms taken by the tow-net from the surface of St. Andrews Bay, where, in July and August, they abound in great numbers, have the body wholly enveloped in a transparent shell, and the various organs are still very rudimentary. By the time they sink to the bottom, the foot, byssus gland, revolving otoliths, liver, and gill-papillæ are well seen. The foot, which is ciliated at the tip, adhesive, and extremely extensile, is the means of active locomotion. Amongst the smallest examples of a previous season, many not more than one-eighth of an inch in length contained in their tissue either ova or spermatozoa, presenting no appreciable difference from those of the adults. They were probably not more than a year old.

---

6. *On the Modification of the Trochal Disc of the Rotifera.* *By* Professor A. G. Bourne, *D.Sc., F.L.S.*

It is now a generally accepted theory that this structure is the homologue of the ciliated bands of the larvæ of Echinoderms, Chætopods, Molluscs, &c., and of the tentaculiferous apparatus of Polyzoa and Gephyrea, and is often termed in common with these a 'velum.' This velum presents itself in various stages of complexity. It is found as a single circum-oral ring (*Pilidium*), as a single præ-oral ring (Chætopod larvæ), or as a single præ-oral ring, co-existing with one or

more post-oral rings (Chætopod larvæ, Holothurian larvæ). We may here assume that the ancestral condition was a single circum-oral ring associated with a terminal mouth and the absence of an anus, and that the existence of other rings posterior to this is an expression of metameric segmentation, *i.e.*, a repetition of similar parts. With the development of a prostomiate condition a certain change necessarily takes place in the position of this band; a portion of it comes to lie longitudinally, but it may still remain a single band, as in the larvæ of many Echinoderms. How have the other above-mentioned conditions of the velum come about? How has the præ-oral band been developed? Two views have been held with regard to this question. According to the one view, the fact whether the single band is a præ-oral or a post-oral one depends upon the position in which the anus is about to develop. If the anus develops in such a position that mouth and anus lie upon one and the same side of the band, the latter becomes præ-oral; if, however, the anus develops so that mouth and anus lie upon opposite sides of the band, the band becomes post-oral. If we hold this view, we must consider any second band, whether præ- or post-oral, to arise as a new development. The other view premises that the anus always forms so as to leave the primitive ring or 'architroch' post-oral, *i.e.*, between mouth and anus. Concurrently with the development of a prostomium this architroch somewhat changes its position, and the two lateral portions come to lie longitudinally; these may be supposed to have met in the median dorsal line, and to have coalesced, so as to leave two rings, the one præ-oral (a 'cephalotroch'), the other post-oral (a 'branchiotroch'). This latter may atrophy, leaving the single præ-oral ring, or it may become further developed and thrown into more or less elaborate folds.

The existing condition of the trochal disc or velum in the Rotifera seems to the author to bear out the latter view as to the way in which the modifications of the velum may have come about; further, these results may be well compared with those recently obtained by Selenka in the Sipunculids. The trochal disc in the Rotifera in its simplest condition forms a single circum-oral ring, as in *Microcodon.* This simple ring may be thrown into folds, so forming a series of processes standing up around the mouth; this is the condition in *Stephanoceros.* There are, however, but few forms presenting this simple condition, and it must be remembered that the evidence for the assumption here made is at present inconclusive. This band may, while remaining single and perfectly continuous, become prolonged around a lobe overhanging the mouth—a prostomium. This condition occurs in *Philodina*; the two sides of the post-oral ring do not meet dorsally, but are carried up, and are continuous with the row of cilia lining the 'wheels.' There is thus one continuous ciliated band, a portion which runs up in front of the mouth. This condition corresponds to that of the Auricularian larva. The folding of the band has become already somewhat complicated. We have only to go a slight step further and the prostomial portion of the band becomes separated as a distinct ring, a cephalotroch. We find such a stage in *Lacinularia*, where both cephalotroch and branchiotroch remain fairly simple in shape. In *Melicerta* the branchiotroch is becoming thrown into folds. Lastly, we find that in such forms as *Brachionus* the cephalotroch becomes first convoluted and then discontinuous, and further it may become so reduced as to be represented only by a few isolated tufts. In such a form as *Lindia* the branchiotroch has become reduced to be two small patches at the sides of the head.

---

7. *On Budding in the Oligochæta.* *By* Professor A. G. Bourne, *D.Sc., F.L.S.*

The author, while working at the Naididæ with the view of preparing a monograph upon the group, has been enabled to make a series of observations upon the exact method of formation of the bud. The observations here described were made upon *Nais* (*Stylaria*) *proboscidea*, and there appears to be some variation in the process, as it occurs in different genera or species. In *N. proboscidea*, when budding is about to commence, a slight thickening of one of the septa which separate one cœlomic segment from another occurs. This thickening increases,

the body-wall in the region thickens, and an actual budding region is here formed. This new region elongates and presents a solid appearance. The alimentary canal grows in this region, but the newly-formed portion is at first unpigmented, and may still be detected at a much later period by its lighter colour; its lumen remains, however, all the time, and a continuous line of fæcal matter may be observed.

This budding region divides into two portions. The anterior portion develops numerous setæ, and gives rise to an indefinite number of segments which form the tail of the old worm; the posterior portion develops four pairs of ventral setæ. This development taking place from before backwards, and subsequently at its anterior region, the characteristic proboscis is developed, and the two individuals separate. The budding region usually forms between the 25th and 26th segments, so that the 26th segment of the parent worm becomes the 5th segment of the posterior daughter worm, the four anterior segments of this worm never presenting dorsal setæ. This condition, moreover, obtains in all the individuals, whether sexual or otherwise, of *Nais proboscidea*, i.e., there are four anterior modified (cephalized) segments. The number of such segments varies in different species of the group.

9. *On the Blastopore and Mesoblast of Sabella. By* Professor D'Arcy W. Thompson.

---

10. *On the Annelids of the Genus* Dero. *By* E. C. Bousfield.

The annelids belonging to the genus *Dero* are allied by most of their external characters to the *Naides*, but are distinguished from them—

1. By the absence of eyes.
2. By the absence of corpuscles from the perivisceral fluid.
3. By the termination of the body in a wide membranous expansion bearing four branchial processes.

This expansion, or branchial area, is essentially a prolongation and opening out of the posterior part of the intestine, and is covered on its non-ciliated surface by the general integument of the body. It is highly contractile, this property being due to the presence of numerous stellate muscle-cells between the respiratory and epidermal walls. Between these walls also run the blood-vessels, the arrangement of which is in this part of their course much modified from the type which characterises the genus *Nais*. The abdominal vessel runs along the middle of the branchial area and divides at its termination into two branches, which run round the area, giving off looped branches to the branchial processes (one to each) and also branches which cross the area obliquely. The branches of each side unite in a common trunk, and the two trunks together form the dorsal vessel. The branchial processes are elevations of the ciliated surface of the area, and as already stated contain a looped blood-vessel, this being surrounded by a hollow cone of muscular elements, by means of which the processes are lengthened or shortened at the will of the animal.

Very various accounts are extant with respect to the number of the processes, but in no case do more than four arise from the floor of the area, and sometimes two supplementary ones of much smaller size on the margin of the latter, where it joins the dorsal surface of the body. Wherever a greater number has been described than three pairs, it is due to the fact that the expanded edges of the branchial area, seen in profile, or perpendicularly, have been mistaken for additional ones, and to arrive at a correct estimate it is absolutely necessary to examine the animal without any pressure whatever. The form of the processes varies in different species. It is cylindrical in *D. Perrieri* and *palpigera*; flattened-cylindrical in *latissima*; foliate, with rounded apices, in *philippinensis, limosa,* and *obtusa*;

and in *acuta* the outline is that of a long isosceles triangle, with the sides about two to three times the length of the base.

The chief works on the subject are as follows:—Müller, 'Die Würmen,' &c., 1775 (*digitata*); Rösel, 'Insecten-Belustigung,' 1761 (*palpigera*); D'Udekem, 'Bull. Ac. Roy. Brux.' 1855 (*obtusa* and *digitata*); Semper, 'Arbeit. Zool. Inst. Wurzb.' 1877 (*philippinensis* and *Rodriguezii-palpigera*); Leidy, 'American Naturalist,' 1880 (*limosa*); Vejdovsky, 'System und Morphologie der Oligochaeten,' 1884 (the whole subject); Perrier, 'Arch. de Zool. Experiment,' 1872 (*obtusa ?*). I have not found it possible to identify Müller's species as yet. His figures have been copied by all who have given figures of *D. digitata*, and no trustworthy one exists. Recent writers have only recorded the fact of having found it, or given a verbal description. Perrier's *D. obtusa* is a new species, and I have named it *D. Perrieri* for convenience of reference. *D. latissima* is described for the first time. *D. acuta* is also new. It is probably one of the *two* species figured as *digitata* by Müller. *D. palpigera* of Grebincky was first figured by Rösel (*loc. cit.*), and redescribed as *D. Rodriguezii* by Semper. The latter also described *D. philippinensis*, but did not figure it, so that the identification of it is doubtful; a remark which also applies to *limosa*, of which only a small outline figure is extant. Further investigation may prove that the species which I have described and figured under those names are new British species, in which case all the species included in my diagnosis, except *palpigera*, are British, and to be found near London. Their number will probably be added to as time goes on.

The following is a complete list of known species:—

1. *Dero obtusa.* The processes short, stunted, flat, four in number.
2. *Dero Perrieri.* Four cylindrical processes, well developed.
3. *Dero latissima.* Four long flattened cylindrical processes; the branchial area expanded into two large wings.
4. *Dero palpigera.* The branchial area terminating in two long, non-ciliated tentacles. The branchial processes four long cylindrical, and two shorter supplementary ones.
5. *Dero limosa.* Four foliate processes, of considerable length; two short supplementary cylindrical ones springing from the angles of dorsal lip.
6. *Dero philippinensis.* Characters as *limosa*, but the supplementary processes springing from a common root.
7. *Dero digitata.* The last segment terminating in two very long processes; four branchial processes.
8. *Dero acuta.* Characters as *limosa*, but the four branchial processes long and triangular, and the area convex in full expansion, with everted edges.

The foregoing descriptions apply to the asexual form; I have only seen the sexual form of the second and third species named.

14. *On some of our Migratory Birds, as first seen in Aberdeenshire.* By JAMES TAYLOR.

Some notes on the first arrival of our summer visitants among birds, so as to give some idea of spring migratory movements. The migration of birds and its causes have occupied the thoughts of eminent ornithologists. It is not our purpose to understand the principle of instinctive movements, but sufficient to say that

many of these may be traced to the laws which regulate the movements of animal economy and directed by their constitutional impulses, as one class of birds seeks more genial climates before the approach of winter, and where their food supplies can be obtained, and on the other, when the storms and frost of winter have been removed, those wandering world-wide citizens find fields and pastures new. It is only their first appearance that can be noticed and noted with care, and thus form an index of their certain movement, and that times and season are not things of chance. Although they make their appearance under different surroundings, their departure is not so easily noticed because in some cases they leave one by one, or in small flocks, and if like the lapwings, the birds old and young gather from July to October into larger and larger flocks of several hundreds, and perhaps seen to-day and to-morrow all have left, without any apparent cause either of food or climatic conditions. Their spring and autumn movements are like their call-notes, breeding-notes, or song-notes; they are constitutional, and manifest themselves when required. We might as well say it is instinct that causes a flower to bloom and assume its natural and inherent colours; the impulses are constitutional, and manifest themselves from earliest life; they are not simple but compound, connected with their physical and procreative functions relating to each animal's life-history and worked into their brain system, and thus become reproduced, in successive generations it becomes stereotyped, so that in most cases external influences have little or no effect, either to cause or retard these migratory movements. True, these outward conditions may quicken or lengthen these movements, but they can neither stop nor arrest them, and even by their destructive influence lessen their number, as under favourable conditions may increase them. And this is true in migratory birds in all parts of the world when their lines of migrations can be traced. Many years ago, when passing through these migratory lines in Arctic seas, we have observed them in their long journeys to their breeding and feeding grounds, both in spring and on their return south in autumn, from the small red-polled linnets, *Linaria borealis.* Gould, the snow bunting, *Plectrophanes nivalis,* Linn., and the Lapland lark bunting, *P. Lapponica,* Seb., and also the large birds both land and sea, such as the peregrine falcon, the cormorant, *Phalacrocorax carbo,* Steph. It is a well-known fact that many of the smaller land birds are caught in the rigging of ships, and some of the larger if the storm of snow or rain with frost continues sufficiently long, the cause of which is frozen ice or snow that accumulates on their feathers so much increasing their weight that flight becomes impossible, and they perish and vast numbers die. Again, in aquatic birds the cause is different from that. During a snow storm they lose the ice-coat, from whatever cause they from their low mode of flight under such often travel far on the land, and strike against objects and thus perish, to be understood from the accounts of lighthouses and ships. In our temperate climate one of the chief causes of delay and loss of life among migratory birds is rain and wet misty fog, the one a storm of wind and rain, the other a long continuance of dull foggy mist when almost everything is invisible, the birds become weighted by the accumulation of water on their feathers, so that they find it impossible to continue their flight, sink down from exhaustion in the sea, perish on the land, die from exhaustion and want of food. One fact well known is, that during foggy weather the young jackdaws and hooded crows are caught in large numbers, because when once wetted with dew they cannot rise. It is often by this means that the arrival of our migratory birds is delayed, but at the same time it is remarkable how little difference there is, taking one year with another. Climatic causes tend from accident to diminish their number rather than affect the regularity of their visits. Another point of equal importance is their departure, but the means of ascertaining it is more difficult, because some birds move in large bodies, while others move in small flocks. If these remarks give any interest to the subject of the arrival and departure of our migratory birds over the country, it in time will add much to our knowledge of their life-history and habits.

Supplementary Meeting.—ANATOMY.

1. *On the Connection of the Os odontoidium with the centrum of the axis vertebra. By* Professor D. J. Cunningham, *F.R.S.*

2. *On the Curvature of the Spine in the Fœtus and Child. By* Dr. Johnston Symington.

3. *On the Bronchial Syrinx of the Cuculidæ and Caprimulgidæ. By* Frank E. Beddard, *M.A., F.R.S.E.*

In this paper the author called attention to the bronchial syrinx hitherto only known in *Crotophaga* and *Steatornis;* it was found to be present in other cuckoos and goatsuckers, and showed a parallel series of modifications in both groups.

4. *Contributions to the Structure of the Oligochæta.*[1] *By* FRANK E. BEDDARD, *M.A., F.R.S.E.*

The present paper is a brief abstract of certain results obtained from the study of a number of different genera and species of earthworms lately received from New Zealand, the Philippine Islands, and the Cape Colony, through the kindness of Professor T. J. Parker, Mr. H. E. Barwell, and the Rev. G. R. Fisk.

(1) *Nephridia.*—Perrier has called attention to a remarkable inconstancy in the position of the nephridial pores in different genera of earthworms. In *Lumbricus* and other genera the external pores are placed near to the more dorsal pair of setæ in all the segments of the body; in *Anteus* the nephridial pores have a similar relation to the ventral pair of setæ; finally in *Pontodrilus* the nephridial apertures alternate in position from segment to segment, sometimes being placed by one of the dorsal, at other times by one of the ventral pair of setæ. These facts seem to indicate the typical presence in earthworms of two series of nephridia each corresponding to one of the two pairs of setæ—an hypothesis originally put forward by Lankester. Other earthworms besides *Pontodrilus* present this same alternation in the position of the nephridial pores; in two species of *Acanthodrilus* (*A. novæzelandiæ*, n. sp., *A. dissimilis*, n. sp.) the same series of facts were observed, but in these two species the dorsal and the ventral series of nephridia differed not merely in their position but also in their structure, which latter fact perhaps tends to still further support the hypothesis referred to above. The hypothesis of a single nephridium to each pair of setæ may be true enough for those earthworms where the setæ are disposed in pairs, but it is not sufficient to account for the relations of the nephridia described by Perrier in *Pontodrilus*. Here the setæ are in eight nearly equidistant longitudinal rows, other nephridial pores alternate not only from pair to pair of setæ but from seta to seta of each pair, seeming to be the remnant of a series of nephridia to each one of the setæ. That this is really the case is proved by the structure of another *Acanthodrilus* (*A. multiporus*, n. sp.) where the setæ are similarly disposed in eight longitudinal rows of single setæ, to each of which corresponds a nephridial tube and external orifice; in the anterior region of the body the nephridial tubules branch and open by a multitude of orifices forming a continuous ring round each segment between the setæ. The presence of more than a single pair of nephridia to each segment has already been noticed by Eisig in certain Capitellidæ, and the ducts have been stated by W. Fischer to branch in the same way that has been described in *Acanthodrilus multiporus*.

(2) *Spermathecæ.*—The spermathecæ of earthworms are in some species, as in *Lumbricus*, simple spherical sacs; in other species they are furnished with one or more diverticula. Sometimes the diverticula come to open into the exterior independent of the spermathecæ, as in certain species of *Perichæta*. In *Microchæta*, a large worm from the Cape Colony, there are no spermathecæ like those of other earthworms, but a number of minute pouches in four segments of the body, varying from one to four. These appear to correspond to the accessory pouches or diverticula of other species, and are placed close to the nephridia of their segments. They have in fact much the same relation to the nephridium as the diverticula of *Perichæta aspergillum* (Perrier) have to the spermathecæ, which is a further argument in favour of regarding the spermathecæ as modified nephridia. In *Acanthodrilus multiporus*, *novæzelandiæ*, and *dissimilis*, the spermathecæ are furnished with diverticula which vary in number, but are characteristic for the species. In every case these diverticula differ in their minute structure from the spermathecæ; and the fact that they are invariably packed with spermatozoa while the spermathecæ are as invariably devoid of spermatozoa indicates that their share in the process of fecundation differs from that of the spermathecæ.

(3) *Dorsal Blood-vessel.*—Dr. Vejdovsky has recorded the fact that in *Criodrilus* the dorsal vessel originates from two rudiments which at first form two distinct tubes and only subsequently coalesce. In certain earthworms the (presumably)

[1] See No. 238, *Proc. Roy. Soc.*

embryonic condition persists throughout life. In *Megascolex* and *Microchæta* the anterior section of the dorsal vessel is double, the two vessels fusing together where they traverse the mesenterics. In *Acanthodrilus novæzelandiæ* the dorsal vessel is double throughout the whole body, the two tubes becoming fused as in *Megascolex* at the mesenterics. In *A. multiporus* the primitive condition is more completely retained, since there are two dorsal vessels which remain distinct as far as the anterior extremity, and do not fuse where they traverse the mesenterics.

---

5. *On the Cervical Vertebræ in* Balæna mysticetus, *&c.* *By* Professor STRUTHERS, *M.D., LL.D.*

Eight specimens of *Mysticetus* showed the bodies completely consolidated, even in the young state, with external indications. In some the first dorsal also united. Superior and inferior transverse processes slender and partially united externally. From his dissections of the soft parts in the Finners, the author could recognise the three stages of these transverse processes, the nerve-groove stage internally on the superior processes, externally on the inferior. The pedicles are much and variously atrophied.

Numerous specimens of *Globicephalus* showed the stages of consolidation. The rudimentary bodies, though very thin, have their epiphyses. In the young the line between the atlas and axis is distinct. In a young specimen the change of position of the transverse processes in relation to the neuro-central suture between the 8th and 10th dorsal vertebræ is well seen.

Dissections of *Beluga* and *Monodon* (Narwhal) showed the deficient bony transverse processes to be fully represented by fibrous cords and bands completing the rings.

---

6. *On the Development of the Foot of the Horse.* *By* Professor STRUTHERS, *M.D., LL.D.*

Attention is called to the fact that the epiphysis of the rudimentary metacarpal and metatarsal bones is not situated at the upper or functional end, but, as in the case of the great metacarpal and metatarsal, at the lower end, here rudimentary. From this a ligament proceeds, expanding in a fascia. The position of this epiphysis is a significant fact, as a link in the chain of evidence of the descent of the horse. It had its use here in the hipparion and other forms which preceded the horse of the present day. The sections of the feet of young horses exhibited by the author also showed that the pastern bone, or first phalanx, has an epiphysis at the distal as well as at the proximal end, the distal epiphysis consolidating early. In the course of this paper, the author showed a specimen of polydactyly in the horse, the additional toe about one third the size of the main toe.

7. *On the Development of the Vertebræ of the Elephant.* *By* Professor STRUTHERS, *M.D., LL.D.*

On the anterior vertebræ the neural arches meet below so as to shut out the bodies from forming any part of the spinal canal. The bodies are buried an inch deep by this mesial meeting of the neurapophyses. This diminishes backwards, the bodies at length rising to form part of the wall of the spinal canal. The vertebræ exhibited were from an elephant, said by the keeper to have been about thirty years of age.

8. *On the Kidneys of Gasteropoda and the Renal duct of Paludina.* *By* W. B. BENHAM.

Section E.—GEOGRAPHY.

President of the Section—General J. T. Walker, C.B., R.E., LL.D., F.R.S.

[For General Walker's Address, see p. 1106.]

THURSDAY, SEPTEMBER 10.

The following Papers were read:—

1. *The Indian Forest School. By* Major F. Bailey, *R.E., F.R.G.S.*

It is only within the last twenty-five years that a special State Department has administered the Indian forests. The staff was at first composed of men who had received no professional education, but they were able to do all that was then needed, and they accomplished work of great value. As a result of their work the State became possessed of large forest areas, from which a permanent supply of produce had to be secured, and which had therefore to be managed systematically. But at this time nothing was known of systematic forestry in England or in India, and an arrangement was made in 1866 under which candidates for the Indian Forest Service were trained on the Continent. The arrangement then made with the French Government is still in force, but it has now been decided to undertake the instruction in England. Great progress has been made in Indian forestry, and this is mainly due to the professionally-trained men with whom the Forest Department has been recruited; but up to 1869 nothing had been done towards the education of the subordinate ranks. As work requiring professional skill became necessary over large areas, it was found that the 'divisions' must be broken up into a number of smaller executive charges under natives of the country, and that they must receive a professional education. In 1869 Mr. Brandis made proposals to organise the subordinate grades and to train men at the Civil Engineering Colleges, and several other attempts were made in the same direction, but without marked success.

In 1878 Mr. Brandis proposed to establish a Central Forest School, and his proposals were accepted by Government. The chief object of the school was to prepare natives of India for the executive charge of forest ranges, and to qualify them for further promotion, but it was hoped that it might ultimately be used to train candidates for the controlling branch. The chief forest officers of provinces were to select candidates and send them to be trained at the school, none but natives of India being admitted. A number of forests near Dehra Dun were grouped together as a training ground and placed under a separate conservator, who was also appointed director of the school; a board of inspection was also appointed. The first theoretical course was held in 1881, and courses have been held every year since then.

The present system is that the candidates, who must be in robust health, are selected by conservators of forests or by the director of the school. They must serve in the forests for at least twelve months before entering the school. Candidates for the ranger's certificate must have passed the entrance examination of an Indian University on the English side; candidates for the forester's certificate must have passed a lower examination. The course of training for these two classes extends over eighteen and twelve months respectively. Men who gain the certificates return

to their provinces, and are employed there. The course of instruction for the rangers' class embraces vegetable physiology, the elements of physics and chemistry, mathematics, road-making and building, surveying, sylviculture, working plans, forest utilisation, forest botany, the elements of mineralogy and geology, forest law and the elements of forest etiology. The course for foresters is much more simple. The preparation of manuals is in progress, and a library, museum, chemical laboratory, observatory and forest garden have been established.

The period of probation in the forest before entry into the school has a twofold object: firstly, to enable the theoretical course to be understood; secondly, to eliminate men who are unsuited to a forest life before time and money have been spent on their training. As a rule, the students are *employés* of the Forest Department, and they draw their salaries and maintain themselves while at the school; no instruction fees being charged. It would not at present be possible to get candidates whose maintenance and education are entirely paid for by their friends. Nine men who have left the school hold appointments worth from 125*l.* to 200*l.* a year, and this ought to draw eligible candidates. Conservators of forests say that the men trained at the school are markedly superior to their untrained comrades. The area of reserved forests has largely increased of late, and the prospects of the students are very good. During the session of 1884 there were forty-six students of all classes at the school, of whom eight were from Madras and seven from native States, the chiefs of which have been induced by the establishment of the school to take measures for the protection of their forests. The school has now been made an imperial institution, and this is a great advantage in every way. The expenses of the school in 1884 are said to have been 1,911*l.*

2. *Brazil.* *By* Colin Mackenzie, *F.R.G.S.*

The author gave an account of the physical geography of Brazil, of its resources and inhabitants. He contrasted the vast area of the country and its scant population, and said that if peopled as densely as Europe it would hold five hundred million souls instead of ten millions, as at present.

3. *On the Progress of African Philology.* *By* R. Needham Cust, *F.R.G.S.*

Taking Dr. Latham's paper on the subject, read at the meeting of the British Association at Oxford in 1847, as a starting-point, Mr. Cust showed how, during the last thirty-eight years, African philology, or linguistic geography, had extended to a marvellous degree, and, under the impetus given to the study of African languages by missionaries and travellers, new additions were being made every year to our knowledge.

4. *On the Changes which have taken place in Tunis since the French Protectorate.* *By* Lieut.-Colonel R. L. Playfair.

The author did not attempt to give a history of the events which led to the treaty of the Kasr-es-Saeed, by which the Bey lost his independence, and the actual government of the country became vested in the French Resident-General. After a few remarks on the manner in which the French are in the habit of governing their colonies, and the disfavour in which the foreign element is held, he bore his willing testimony to the important work of civilisation and improvement which is now being carried on in Tunis. He alluded to the fact that he had been the first foreigner to pass through the celebrated Khomair country in 1876, when it was simply a blank space on the maps then existing, and when neither private travellers nor Beylical officials were permitted to cross its frontiers.

He again visited this country last year, and traversed nearly the same ground, but on this occasion over admirably constructed carriage roads, passing from the Algerian frontier to Ain-Draham, a military station in the centre of the Khomair mountains, and thence down to the valley of the Medjerda through which now

runs a railway from Souk Ahras in Algeria to Tunis. He passed several important Roman cities, such as Simittu Colonia at the famous quarries of Numidian marble, and Bulla Regia, near the station of Souk-el-Arba. He visited El Baja on both occasions, and found it, on the former, a picturesque but fever-stricken town, and on the latter, clean and healthy, with the old Byzantine citadel transformed into modern French barracks.

At Tunis itself good roads are being constructed, and a modern French town is being built between the native city and the lake. But the picturesque Arab bazaars, which are a never-ending source of delight to the traveller, are quite untouched. Land is being rapidly brought under cultivation, taxes are being reduced or abolished, and a very important measure of reform is about to be effected, based on the famous Torrens Act, by which real property will become as easily transferable as a bank share. This will be done without trouble or violence, and it will be optional for all owners of property either to adopt the new system or to retain the old one. He detailed the steps which are being taken for the spread of public instruction both by the Government authorities and the eminent prelate who governs the Church in North Africa, Cardinal Lavigérie, and the means adopted by the Government for the archæological exploration of the Regency, still almost a virgin field. And lastly he gave a short summary of the daring project of Commandant Roudaire for the creation of an inland sea by the submersion of the Sahara.

FRIDAY, SEPTEMBER 11.

The PRESIDENT delivered the following Address:—

MY predecessors in this chair have claimed for geography a range of science which may be said to be practically unlimited; for it comprehends the history of the earth itself, and of all the life to be met with on the surface of the earth, from the first beginnings of things, and through their subsequent development onwards to their present conditional status; it is associated in a greater or less degree with every other department of knowledge, and is a remarkable exemplification of the mutual interdependence and correlation of the physical sciences, for while all other branches of science are incomplete without some knowledge of geography, it is incomplete without some knowledge of each and all of them.

Such claims on behalf of geography would, not many years ago, have been considered extravagant and exaggerated; a popular encyclopædia which is still of some note defines geography to be simply the science which describes the surface of the earth, and somewhat querulously complains that geographical treatises contain matter not unfrequently taken from statistics, natural philosophy, and history which it declares to be irrelevant and not properly admissible into such treatises. And in a popular sense geography is still commonly suggestive only of such a knowledge of locality as may be acquired from maps and charts, with their graphical delineations of whatever exists on the surface of the earth, and of the various natural or artificial boundary lines of the peoples and states between whom the surface is divided. But the British Association and the Royal Geographical Society have successfully maintained that scientific geography is not restricted in its scope to a mere knowledge of locality—though that in itself is a very important factor in whatever appertains to the intercourse and mutual relations of mankind—but embraces all that relates to the structure and existing configuration of the earth, and takes cognizance of the varied conditions of all the life, both animal and vegetable, which is nurtured and supported by the earth; it studies the side lights which the general configuration of surface throws on the character of each locality as a home and support of life, and it examines with special interest the influence which that character has exerted on the social and political conditions of different races and peoples.

And geography does not merely devote its attention to the existing order of things as now displayed to our gaze; in alliance with geology it studies the history

of a distant past, when the features of the earth's surface were not precisely as now, and lands which we see high above our horizon lay deep beneath the ocean, and life existed in other forms, whose mute records we possess in the fossils—the *likha-kân*, or written stones as they are significantly called by the people of Afghanistan—which, after long lying entombed among the rocks, are presented to modern sight as revelations of life's early dawn; it investigates what Baron Richtofen describes as the reciprocal causal relations of the three kingdoms—land, water, and atmosphere; it seeks to determine the processes by which in some parts of the globe continents were built up with their varied sculpture of mountain and valley, of highly elevated plateau and low lying plain, of lakes and inland seas, and great river systems,—while in other parts land was depressed below the sea level, or broken up into the islands which are now dotting the surface of the ocean; and it endeavours to trace a process of continuous evolution of life from the primary and simplest types which perished in the early ages of the earth's history, to the latest and most highly developed types which are now flourishing around us. Going back still further it searches for evidence of the first beginnings of the material universe; it looks beyond the orbit of the most distant planet of the solar system, and scrutinises the boundless regions of stellar space to find, in the widely scattered particles of the nebulæ, the beginnings of new solar systems and new worlds such as ours; there it may be said to behold as in a mirror the formation of our own planet as a fluid igneous mass thrown off with great velocity from its sun, and rapidly revolving, and then becoming spheroidal, and slowly cooling and solidifying, and finally acquiring the crust which was to become an abode for life, the stage whereon man was to play out the drama of his planetary existence, and be held all the while fast imprisoned and out of touch with the surrounding universe.

More than this we would seek to know, but in vain; in passing from the early dawn of matter to that of life, science finds its career of wonderful achievement in the one direction exchanged for failure and disappointment in the other; it cannot discover the origin of life in any of its existing material forms, nor trace to its birthplace the spiritual life which exerts such an influence on what is material; it cannot ascertain whether man had a prior existence as different from his present existence as the first beginnings of his planet home differed from its present condition; it cannot gauge the truth of the poet's prescient conception that

> 'Our birth is but a sleep and a forgetting;
> The soul that rises with us, our life's star,
> Hath had elsewhere its setting
> And cometh from afar.'

It whispers faint suggestions regarding the possible future of the planet; but when questioned as to what is to follow the coming soul's setting of man, the planet's chief glory and dignity, it has nothing to reply, but is hopelessly dumb and inarticulate.

Scientific geography embraces a wide range of subjects, wider than can be claimed for any other department of science. Thus the President of this Section has a vast field from which to gather subjects for his opening address. I shall, however, restrict my address to the subject with which I am most familiar, and give you some account of the Survey of India, and more particularly of the labours of the trigonometrical or geodetic branch of that survey, in which the best years of my life have been passed.

I must begin by pointing out that the survey operations in India have been very varied in nature, and constitute a blending together of many diverse ingredients. Their origin was purely European, nothing in the shape of a general survey having been executed under the previous Asiatic Governments; lands had been measured in certain localities, but merely with a view to acquiring some idea of the relative areas of properties, in assessing on individuals the share of the revenue levied on a community; but other factors than area—such as richness or poverty of soil, and proximity or absence of water—influenced the assessment, and often in a greater degree, so that very exact measurements of area were not wanted for revenue purposes, and no other reason then suggested itself why lands should be accurately

measured. The value of accurate maps of individual properties, with every boundary clearly and exactly laid down, was not thought of in India in those days, and indeed has only of late years began to be recognised by even the British Government. The idea of a general geographical survey never suggested itself to the Asiatic mind. Thus when Englishmen came to settle in India, one of their first acts was to make surveys of the tracts of country over which their influence was extending; and as that influence increased, so the survey became developed from a rude and rapid primary delineation of the broad facts of general geography, to an elaborately executed and artistic delineation of the topography of the country, and in some provinces to the mapping of every field and individual property. Thus there have been three orders or classes of survey, and these may be respectively designated geographical, topographical, and cadastral; all three have frequently been carried on *pari passu,* but in different regions, demanding more or less elaborate survey according as they happened to be more or less under British influence. There is also the Great Trigonometrical or Geodetic Survey, by which the graphical surveys are controlled, collated, and co-ordinated, as I will presently explain.

Survey operations in India began along the coast-lines before the commencement of the seventeenth century, the sailors preceding the land surveyors by upwards of a century. The Directors of the East India Company, recognising the importance of correct geographical information for their mercantile enterprises, appointed Richard Hakluyt, Archdeacon of Westminster, their historiographer and custodian of the journals of East Indian voyages, in the year 1601, within a few weeks of the establishment of the company by Royal Charter. Hakluyt gave lectures to the students at Oxford, and is said by Fuller to have been the first to exhibit the old and imperfect maps and the new and revised maps for comparison in the common schools, 'to the singular pleasure and great contentment of his auditory.' The first general map of India was published in 1752 by the celebrated French geographer D'Anville, and was a meritorious compilation from the existing charts of coast-lines and itineraries of travellers. But the Father of Indian Geography, as he has been called, was Major Rennell, who landed in India as a midshipman of the Royal Navy in 1760, distinguished himself in the blockade of Pondicherry, was employed for a time in making surveys of the coast between the Paumben Passage and Calcutta, was appointed Surveyor of the East India Company's dominions in Bengal in 1764, was one of the first officers to receive a commission in the Bengal Engineers on its formation, and in 1767 was raised to the position of Surveyor-General. Bengal was not in those days the tranquil country we have known it for so many years, but was infested by numerous bands of brigands who professed to be religious devotees, and with whom Rennell came into collision in the course of one of his surveying expeditions, and was desperately wounded; he had to be taken 300 miles in an open boat for medical assistance, the natives meanwhile applying onions to his wounds as a cataplasm. His labours in the survey of Bengal lasted over a period of nineteen years, and embraced an area of about 300,000 square miles, extending from the eastern boundaries of Lower Bengal to Agra, and from the Himalayas to the borders of Bandelkand and Chota Nagpur. Ill-health then compelled him to retire from the service on a small pension and return to England; but not caring, as he said, to eat the bread of idleness, he immediately set himself to the utilisation of the large mass of geographical materials laid up and perishing in what was then called the India House; he published numerous charts and maps, and eventually brought out his great work on Indian Geography, the 'Memoir of a map of Hindostan,' which went through several editions; this was followed by his Geographical System of Herodotus, and various other works of interest and importance. His labours in England extended over a period of thirty-five years, and their great merits have been universally acknowledged.

Rennell's system of field-work in Bengal was a survey of routes checked and combined by astronomical determinations of the latitude and the longitude, and a similar system was adopted in all other parts of India until the commencement of the present century. But in course of time the astronomical basis was found to be inadequate to the requirements of a general survey of all India, as the errors in the astrono-

mical observations were liable materially to exceed those of the survey, if executed with fairly good instruments and moderate care. Now this was no new discovery, for already early in the eighteenth century the French Jesuits who were making a survey of China—with the hope of securing the protection of the Emperor, which they considered necessary to favour the progress of Christianity—had deliberately abandoned the astronomical method and employed triangulation instead. Writing in the name of the missionaries who were associated with him in the survey, Père Regis enters fully into the relative advantages of the two methods, and gives the trigonometrical the preference, as best suited to enable the work to be executed in a manner worthy the trust reposed in them by a wise prince, who judged it of the greatest importance to his State. 'Thus,' he says, 'we flatter ourselves we have followed the surest course, and even the only one practicable in prosecuting the greatest geographical work that was ever performed according to the rules of art.'

What was true in those days is true still; points whose relative positions have been fixed by any triangulation of moderate accuracy present a more satisfactory and reliable basis for topographical survey than points fixed astronomically. Though the lunar theory has been greatly developed since those days by the labours of eminent mathematicians, and the accuracy of the lunar tables and star catalogues is much increased, absolute longitudes are still not susceptible of ready determination with great exactitude; moreover, all astronomical observations, whether of latitude or longitude, are liable to other than intrinsic errors, which arise from deflection of the plumb-line under the influence of local attractions, and which of themselves materially exceed the errors that would be generated in any fairly executed triangulation of a not excessive length, say not exceeding 500 miles.

Thus at the close of the last century Major Lambton, of the 33rd Regiment, drew up a project for a general triangulation of Southern India. It was strongly supported by his commanding officer—Colonel Wellesley, afterwards the Duke of Wellington—and was readily sanctioned by the Madras Government; for a large accession of territory in the centre of the peninsula had been recently acquired, as the result of the Mysore campaign, by which free communication had been opened between the east and west coasts, of Coromandel and Malabar; and the proposed triangulation would not merely furnish a basis for new surveys, but connect together various isolated surveys which had already been completed or were then in progress. The Great Trigonometrical Survey of India owes its origin as such, and its simultaneous inception as a geodetic survey, to Major Lambton, who pointed out that the trigonometrical stations must needs have their latitudes and longitudes determined for future reference just as the discarded astronomical stations, not however by direct observation, but by processes of calculation requiring a knowledge of the earth's figure and dimensions. But at that time the elements of the earth's figure were not known with much exactitude, for all the best geodetic arcs had been measured in high latitudes, the single short and somewhat questionable arc of Peru being the only one situated in the vicinity of the equator. Thus additional arcs in low latitudes, as those of India, were greatly needed and might be furnished by Lambton. He took care to set this forth very distinctly in the programme which he drew up for the consideration of the Madras Government, remarking that there was thus something still left as a desideratum for the science of geodesy, which his operations might supply, and that he would rejoice indeed should it come within his province 'to make observations tending to elucidate so sublime a subject.'

Lambton commenced operations by measuring a base line and a small meridional arc near Madras, and then, casting a set of triangles over the southern peninsula, he converted the triangles on the central meridian into a portion of what is now known as the Great Arc of India, measuring its angles with extreme care, and checking the triangulation by base lines measured at distances of 2 to 3 degrees apart in latitude. His principal instruments were a steel measuring chain, a great theodolite, and a zenith sector, each of which had a history of its own before coming into his hands. The chain and zenith sector were sent from England with

Lord Macartney's Embassy to the Emperor of China, as gifts for presentation to that potentate, who unfortunately did not appreciate their value and declined to accept them; they were then made over to Dr. Dinwiddie, the astronomer to the embassy, who took them to India for sale. The theodolite was constructed in England for Lambton, on the model of one in use on the Ordnance Survey; on its passage to India it was captured by the French frigate, the *Piemontaise*, and landed at Mauritius, but eventually it was forwarded to its destination by the chivalrous French Governor, De Caen, with a complimentary letter to the Governor of Madras.

Lambton was assisted for a short time by Captain Kater, whose name is now best known in connection with pendulum experiments and the employment of the seconds' pendulum as a standard of length; but for many years afterwards he had no officer to assist him. At first he met with much opposition from advocates of the discarded astronomical method, who insisted on its being sufficiently accurate and more economical than the trigonometrical. But he was warmly supported by Maskelyne, the Astronomer-Royal in England; and he soon had an opportunity of demonstrating the astronomical method to be fallacious, for its determination of the breadth of the peninsula in the latitude of Madras was proved by the triangulation to be forty miles in error. Still, for several years he never received a word of sympathy, encouragement, or advice either from the Government or from the Royal Society. A foreign nation was the first to recognise the importance of his services to science, the French Institute electing him a corresponding member in 1817. After this, honours and applause quickly followed from his own countrymen. In 1818 the then Governor-General of India—the Marquis of Hastings—decided that the survey should be withdrawn from the supervision of a local government and placed under the Supreme Government, with a view to its extension over all India, remarking at the same time that he was 'not unaware that with minds of a certain order he might lay himself open to the idle imputation of vainly seeking to partake the gale of public favour and applause which the labours of Colonel Lambton had recently attracted;' but as the survey had reached the northern limits of the Madras Presidency, its transfer to the Supreme Government, if it was to be further extended, had become a necessity. He directed the transfer to be made, and the survey to be called in future the Great Trigonometrical Survey of India. Noticing that the intense mental and bodily labour of conducting it was being performed by Lambton alone, that his rank and advancing age demanded some relief from such severe fatigue, and farther, that it was not right that an undertaking of such importance should hang on the life of a single individual, the Governor-General appointed two officers to assist him—Captain Everest, as chief assistant in the geodetic operations; and Dr. Voysey, as surgeon and geologist. Five years afterwards Lambton died, at the age of 70. The happy possessor of an unusually robust and energetic constitution and a genial temperament, he seems to have scarcely known a day's illness, though he never spared himself nor shrank from subjecting himself to privations and exposure which even Everest thought reckless and unjustifiable. These he accepted as a matter of course, saying little about them, and devoting his life calmly and unostentatiously to the interests of science and the service of his country.

Everest's career in the survey commenced disastrously. He was deputed by Lambton to carry a triangulation from Hydrabad, in the Nizam's territory, eastwards to the coast, crossing the forest-clad and fever-haunted basin of the Godavery river, a region which he described as 'a dreadful wilderness, than which no part of the earth was more dreary, desolate, and fatal.' Indignant at being taken there, his escort, a detachment of the Nizam's troops, mutinied, and soon afterwards he and his assistants, and almost all the men of his native establishment, were stricken down by a malignant fever; many died on the spot, and the survivors had to be carried into Hydrabad, whence litters and vehicles of all descriptions, and the whole of the public elephants, were despatched to their succour. To recover his health Everest was compelled to leave India for a while and proceed to the Cape of Good Hope, where he remained for three years. He availed himself of the opportunity to inspect Lacaille's meridional arc, which, when compared with the

arcs north of the equator, indicated that the opposite hemispheres of the globe were seemingly of different ellipticities. He succeeded in tracing this anomaly to an error in the astronomical amplitude of the arc, which had been caused by deflection of the plumb-line at the ends of the arc, under the influence of the attraction of neighbouring mountains. Thus he became aware of the necessity of placing the astronomical stations of the Indian arcs at points where the plumb-line would not be liable to material deflection by the attraction of neighbouring mountain ranges. Shortly after his return to India Lambton died, and Everest succeeded him, and immediately concentrated his energies on the extension of the Great Arc northwards. He soon came to the conclusion that his instrumental equipment, though good for the time when it was procured, and amply sufficient for ordinary geographical purposes, was inadequate for the requirements of geodesy, and generally inferior to the equipments of the geodetic surveys then in progress in Europe. He therefore proceeded to Europe to study the procedure of the English and French surveys, and also to obtain a supply of new instruments of the latest and most improved forms. The Court of Directors of the Honourable East India Company accorded a most liberal assent to all his proposals, and gave him *carte blanche* to provide himself with whatever he considered desirable to satisfy all the requirements of science.

Everest returned to India with his new instrumental equipment in 1830, a year that marks the transition of the character of the operations from an order of accuracy which was sufficient as a basis for the graphical delineation of a comparatively small portion of the earth's surface, to the higher precision and refinement which modern geodesists have deemed essentially necessary for the determination of the figure and dimensions of the earth as a whole. He immediately introduced an important modification of the general design of the principal triangulation, which up to that time had been thrown as a network over the country on either side of the Great Arc, as in the English survey and many others; but he abandoned this method, and, adopting that of the French survey instead, he devised a system of meridional chains, to be carried at intervals of about 1° apart, and tied together by longitudinal chains at intervals of about 5°, the whole forming, from its resemblance to the homely culinary utensil with which we are all familiar, what has been called the gridiron system in contradistinction to the network. The entire triangulation was to rest on base-lines to be measured with the new Colby apparatus of compensation bars and microscopes which had been constructed to supersede the measuring chain the Emperor of China had rejected; the base-lines were to be placed at the intersections of the longitudinal chains of triangles with the central meridional or axial chain, and also at the further angles of the gridirons on each side. Latitudes were to be measured at certain of the stations of the central chain, with new astronomical circles in place of the old zenith sector, to give the required meridional arcs of amplitude. Two radical improvements on all previous procedure were introduced in the measurement of the principal angles, one affecting the observations, the other the objects observed. The great theodolites were manipulated in such a manner as not merely to reduce the effects of accidental errors by numerous repetitions in the usual way, but absolutely to eliminate all periodic errors of graduation by systematic changes of the position of the azimuthal circle relatively to the telescope, in the course of the complete series of measures of every angle. The objects formerly observed had been cairns of stones or other opaque signals; for these Everest substituted luminous signals, lamps by night, and, by day, heliotropes which were manipulated to reflect the sun's rays through diaphragms of small aperture, in pencils appearing like bright stars and capable of penetrating a dense atmosphere through which distant opaque objects could not be seen.

Everest's programme of procedure furnished the guiding principles on which the operations were carried out during the period of half a century which intervened between their commencement under his superintendence and the completion of the principal triangulation under myself. The external chains have necessarily been taken along the winding course of the frontier and coast lines instead of the direct and more symmetrical lines of the meridians and the parallels of latitude. The

number of the internal meridional chains has latterly been diminished by widening the spaces between them, and in two instances a principal chain has been dispensed with because, before it could be taken in hand, a good secondary triangulation had been carried over the area for which it was intended to provide. But these are departures from the letter rather than the spirit of Everest's programme, which has been faithfully followed throughout, first by his immediate successor, Sir Andrew Waugh, and afterwards by myself, thus affording an instance of the impress of a single mind on the work of half a century which is probably unique in the annals of India; for there, as is well known, changes of personal administration are frequent, and are not uncommonly followed by changes of procedure.

The physical features of a country necessarily exercise a considerable influence on the operations of any survey that may be carried over it, and more particularly on those of a geodetic survey, of which no portion is allowed to fall below a certain standard of precision. Every variety of feature, of scenery, and of climate that is to be met with anywhere on the earth's surface between the equator and the arctic regions has its analogue between the highlands of Central Asia and the ocean, which define the limits of the area covered by the Indian survey. Thus in some parts the operations were accomplished with ease, celerity, and enjoyment, while in others they were very difficult and slow of progress, always entailing great exposure, and at times very deadly. In an open country, dotted with hills and commanding eminences, they advanced as on velvet; in close country, forest-clad or covered with other obstacles to distant vision, they were greatly retarded, for there it became necessary either to raise the stations to a sufficient height to overlook all surrounding obstacles, or to render them mutually visible by clearing the lines between them; and both these processes are more or less tedious and costly. There are many tracts of forest and jungle which greatly impeded the operations, not merely because of the physical difficulties they presented, but because they teemed with malaria, and were very deadly during the greater portion of the year, and more particularly immediately after the rainy seasons, when the atmosphere is usually clearest and most favourable for distant observations. At first tracts of forest, covering extensive plains, were considered impracticable; thus Lambton carried his network over the open country, and stopped it whenever it reached a great plain covered with forest and devoid of hills; but Everest's system would not permit of any break of continuity, nor the abandonment of any chain which was required to complete a gridiron; it has been carried out in all its integrity, often with much sacrifice of life, but never with any shrinking on the part of the survey officers from carrying out what it had become a point of honour with them to accomplish, and the accomplishment of which the Government had come to regard as a matter of course. We have already seen how the progress of Everest's first chain of triangles was suddenly arrested, because he and all his people were struck down by malaria in the pestilential regions of the Godavery basin. That chain remained untouched for fifty years; it was then resumed and completed, but with the loss of the executive officer, Mr. George Shelverton, who succumbed when he had not yet reached, but was within sight of, the east coast line, the goal towards which his labours were directed. Many regions, as the basin of the Mahanaddi, the valley of Assam, the hill ranges of Tipperah, Chittagong, Arracan, and Burma, and those to the east of Moulmein and Tennasserim, which form the boundary between the British and the Siamese territories, are covered with dense forest, up to the summits of the peaks which had to be adopted as the sites of the survey stations. As a rule the peaks were far from the nearest habitation, and they could not be reached until pathways to them had been cut through forests tangled with a dense undergrowth of tropical jungle; not unfrequently large areas had to be cleared on the summits to open out the view of the surrounding country. Here the physical difficulties to be overcome were very considerable, and they were increased by the necessity that arose, in almost every instance, of importing labourers from a great distance to perform the necessary clearances. But the broad belt of forest tract known as the Terai, which is situated in the plains at the foot of the Nepalese Himalayas, was the most formidable region of all, because the climate was very deadly for a great portion of the year, and more particularly during the

season when the atmosphere was most favourable for the observations, though the physical difficulties were not so great as in the hill tracts just mentioned, and labour was more easily procurable. Lying on the British frontier, at the northern extremities of no less than ten of the meridional chains of triangles, it had necessarily to be operated in to some extent, and Everest wished to carry the several chains across it, on to the outer Himalayan range, and then to connect them together by a longitudinal chain running along the range from east to west, completing the gridiron in this quarter. But the range was a portion of the Nepalese territories, and all Europeans—excepting those attached to the British embassy at Khatmandu—were debarred from entering any part of Nepal, by treaty with the British Government. Everest hoped that the rulers of Nepal might make an exception in his favour for the prosecution of a scientific survey; and when he found they would not, he urged the Government to compel them to give his surveyors access, at least, to their outlying hills; but he urged in vain, for the Government would not run the risk of embarking in a war with Nepal for purely scientific interests. Thus the connecting chain of triangles—now known as the N.E. Longitudinal Series—had to be carried through the whole length of the Terai, a distance of about 500 miles, which involved the construction of over 100 towers—raised to a height of about 30 feet to overlook the earth's curvature—and the clearance of about 2,000 miles of line through forest and jungle to render the towers mutually visible. It required no small courage on Everest's part to plunge his surveyors into this region; he endeavoured to minimise the risks as much as possible by taking up the longitudinal chain in sections, bit by bit, on the completion of the successive meridional chains, and thus apportioning it between several survey parties, each operating in the Terai for a short time, instead of assigning it to a single party to execute continuously from end to end, as all the other chains of triangles. But notwithstanding these precautions, the peril was great, and the mortality among both officers and men was very considerable; greater than in many a famous battle, says Mr. Clements Markham, in an eloquent passage in his Memoir of the Indian Surveys, in which he claims for the surveyors who were employed on these operations—with no hope of reward other than the favourable notice of their immediate chief and colleagues—merit for more perilous and honourable achievement than much of the military service which is plentifully rewarded by the praises of men and prizes of all kinds.

Everest retired in 1843, and was succeeded by Waugh, who applied himself energetically to the completion of the several chains of triangles exterior to the Great Arc, for which he obtained a substantial addition to the existing equipment of great theodolites. It was under him that the formidable longitudinal series through the Terai, which had been begun by Everest, was chiefly carried out. He personally initiated the determination of the positions and heights of the principal snow peaks of the Himalayan ranges; and he did much for the advancement of the general topography of India, which had somewhat languished under his predecessor, who had devoted himself chiefly to the geodetic operations. He retired in 1861, and I succeeded to the charge of the Great Trigonometrical Survey. The last chain of the principal triangulation was completed in 1882, shortly before my own retirement.

Of the general character of the operations, it may be asserted without hesitation that a degree of accuracy and precision has been attained which has been reached by few and surpassed by none of the great national surveys carried out in other parts of the world, and which leaves nothing to be desired even for the requirements of geodesy; a very considerable majority of the principal angles have been measured with the great 24-inch and 36-inch theodolite, and their theoretical probable error averages about a quarter of a second; of the linear measurements the probable error, so far as calculable, may be taken as not exceeding the two-millionth part of any measured length. And as regards the extent of the triangulation, if we ignore the primary network in Southern India, and all secondary triangulation, however valuable for geographical purposes, we still have a number of principal chains—meridional, longitudinal, and oblique—of which the aggregate length is 17,300 miles, which contain 9,230 first-class angles all observed, and rest on eleven

base-lines measured with the Colby apparatus of compensation bars and microscopes. This prodigious amount of field-work furnishes an enormous mass of interdependent angular and linear measures; and each of these is fallible in some degree, for, great as was the accuracy and care with which they had severally been executed, perfect accuracy of measurement is as yet beyond human achievement; thus every circuit of triangles, every chain closing on a base-line, and even every single triangle, presented discrepancies the magnitude of which was greater or less according as derived from a combination of many, or only of a few, of the fallible facts of observation. Thus, when the field operations were approaching their termination, the question arose as to how these facts were to be harmonised and rendered consistent throughout, which was a very serious matter considering their great number. The strict application of mathematical theory to a problem of this nature requires the adjustment to be effected by the application of a correction to every fact of observation, not arbitrarily, but in such a manner as to give it its proper weight, neither more nor less, in the final investigation, and in this the whole of the facts must be treated simultaneously. That would have involved the simultaneous solution of upwards of 4,000 equations between 9,230 unknown quantities, by what is called the method of minimum squares, and I need scarcely say that it is practically impossible to solve such a number of equations between so many unknown quantities by any method at all. Thus a compromise had to be made between the theoretically desirable and the practically possible. It would be out of place here to attempt to describe the method of treatment which was eventually adopted, after much thought and deliberation; I will merely say that the bulk of the triangulation was divided into five sections, each of which was treated in succession with as close approximation to the mathematically rigorous method as was practically possible; but even then the mass of simultaneous interdependent calculation to be performed in each instance was enormous, I believe greatly exceeding anything of the kind as yet attempted in any other survey. But the happy result of all this labour was that the final corrections of the angles were for the most part very minute, less than the theoretical probable errors of the angles, and thus fairly applicable without taking any liberties with the facts of observation. If the attribute of beauty may ever be bestowed on such things as small numerical quantities, it may surely be accorded to these notable results of very laborious calculations, which, while in themselves so small, were so admirably effective in introducing harmony and precision throughout the entire triangulation.

If now we turn once more to what Lambton calls 'the sublime science of geodesy,' which was held in such high regard by both him and Everest, we shall find that the great meridional arc between Cape Comorin and the Himalayas, on which they laboured with so much energy and devotion, is not the only contribution to that science to which the Indian triangulation is subservient, but every chain of triangles —meridional, longitudinal, or oblique—may be made to throw light either on geodesy, the science of the figure of the earth, or on geognosy, the science of the earth's interior structure, when combined with corresponding astronomical arcs of amplitude. Thus each of the several meridional chains of triangles may be utilised in this way, as their prototype has been, by having latitude observations taken at certain of their stations to give meridional arcs; and the several longitudinal chains of triangles may also be utilised—in combination with the main lines of telegraph—by electro-telegraphic determinations of differential longitudes to give arcs of parallel. When the stations of the triangulation which are resorted to for the astronomical observations are situated in localities where the normal to the surface coincides fairly with the corresponding normal to the earth's figure, the result is valuable as a contribution to geodesy; when the normal to the surface is sensibly deflected by local attraction, the result gives a measure of the deflection which is valuable as a contribution to geognosy.

Having regard to these circumstances, I moved the Government to supply the Trigonometrical Survey with the necessary instruments for the measurement of the supplemental astronomical arcs; and as officers became available on the gradual completion of the successive chains of triangles, I employed some of them in the required determinations of latitude and differential longitude. It so happened that

about the same time geodesists in Europe began to recognise the advantages to science to be acquired by connecting the triangulations of the different nationalities together, and supplementing them with arcs of amplitude. The 'International Geodetic Association for the Measurement of Degrees in Europe' was formed in consequence, and it has been, and is still, actively employed in carrying out this object; in India, however, the triangulation was complete and connected throughout, so that only the astronomical amplitudes were wanting. They are still in progress, but already meridional chains, aggregating 1,840 miles in length, and lying to the west of the Great Arc, have been converted into meridional arcs; and the three longitudinal chains, from Madras to Mangalore, from Bombay to Vizagapatam, and from Kurrachee *viâ* Calcutta to Chittagong, of which the aggregate length is 2,600 miles, have been converted into arcs of parallel. In the former the operations follow the meridional course of the chains of triangles; in the latter they follow the principal lines of the electric telegraph, which sometimes diverge greatly from the direction of the longitudinal chains of triangles, the two only intersecting at occasional points; the astronomical stations are therefore placed at the trigonometrical points which may happen to be nearest the telegraph lines, whether on the meridional or on the longitudinal chains, and their positions are invariably so selected as to form self-verificatory circuits which are usually of a triangular form, presenting three differential arcs of longitude; each of these arcs is measured independently as regards the astronomical work—though for the third arc there is usually no independent telegraph line, but only a coupling of the lines for the first and second arcs—and this has been proved to give such an excellent check on the accuracy of the operations, that it is not too much to say that no telegraphic longitude operations are entirely reliable which have not been verified in some such manner.

Through the courtesy of Colonel Stotherd, Director-General of the Ordnance Survey, I am enabled to exhibit two charts, one of the triangulation of India, the other of that of Europe, which have recently been enlarged to the same scale in the Ordnance Survey Office at Southampton for purposes of comparison. The first is taken from the official chart of the Indian survey, and shows the great meridional and longitudinal chains and Lambton's network of principal triangles, the positions of the base-lines measured with the Colby apparatus, the latitude and the differential longitude stations, the triangular circuits of the longitudinal arcs, the stations of the pendulum and the tidal operations which will be noticed presently, and the secondary triangulations to fix the peaks of the Himalayan and Sulimani ranges, and the positions of Bangkok in Siam and Kandahar in Afghanistan, the extreme eastern and western points yet reached. The chart of the European triangulation has been enlarged from one published by the International Geodetic Association of Europe; in it special prominence is given to the Russian meridional arc, which extends from the Danube to the Arctic Ocean, and is 25° 20′ in length, and to the combined English and French meridional arc, 22° 10′ in length, which extends from the Balearic Island of Formentera in the Mediterranean, to Saxavord in the Shetland Islands. The aggregate length of the meridional arcs already completed in India is about equal to that of the English, French and Russian arcs combined; but the longest in India is about $1\frac{1}{2}$° shorter than the Russian. As regards longitudinal arcs, I believe the two which were first measured in India, and were employed shortly afterwards by Colonel Clarke in his last investigation of the figure of the Earth, are the only ones which have as yet been deemed sufficiently accurate to be made use of in such investigations, though arcs of much greater length have been measured in Europe. It would be interesting, if time permitted, to set forth the salient points of divergence between the systems of the Indian and the European surveys; I will only mention that in the southern part of the Russian arc, for a space of about 8° from the Duna to the Dneister, a vast plain, covered with immense and almost impenetrable forests, presented great obstacles to the prosecution of the work; the difficulty was overcome by the erection of a large number of lofty stations of observation, wooden scaffoldings which were 120 and even as much as 146 feet high, to overlook the forests. In Indian forests, as the Terai on the borders between British and Nepalese territories, the stations were

rarely raised to a greater height than 30 feet, or just sufficient to overtop the curvature, and all trees and other obstacles were cleared away on the lines between them; this was found the most expeditious and economical process. The stations were very substantial, with a central masonry pillar, for the support of a great theodolite, which was isolated from the surrounding platform for the support of the observer. The lofty Russian scaffoldings only sufficed for small theodolites, and they were so liable to shake and vibration that the theodolites had to be fitted with two telescopes to be pointed simultaneously by two observers at the pair of stations, the angle between which was being measured.

All the modern geodetic data of the Indian survey that were available up to the year 1880 were utilised by Colonel A. R. Clarke, C.B., of the Ordnance Survey, in the last of the very valuable investigations of the Figure of the Earth which he has undertaken from time to time. It will be obvious that new data tend to modify in some degree the conclusions derived from previous data, for the figure of so large a globe as our earth is not to be exactly determined from measurements carried over a few narrow belts of its superficies. Thus thirty years ago it was inferred that the equator was sensibly elliptic—and not circular, as had been generally assumed—with its major axis in longitude 15° 34′ east of Greenwich; but later investigations indicate a far smaller ellipticity, and place the major axis in west longitude 8° 15′. More significant evidence of the influence of new facts of observation in modifying previous conclusions is furnished by the French national standard of length, the mètre, which was fixed at the ten-millionth part of the length of the earth's meridional quadrant, as deduced from the best geodetic data available up to the end of the last century; but it is now found to be nearly $\frac{1}{5000}$th part less than the magnitude which it is supposed to represent, the difference being about a hundred times greater than what would now be considered an allowable error in an important national standard of measure.

The Indian survey has also made valuable contributions to geodesy and geognosy in an elaborate series of pendulum observations for determining variations of gravity, which throws light both on the grand variation from the poles to the equator that governs the ellipticity, and on the local and irregular variations depending on the constitution of the interior of the earth's crust. They were commenced in 1865 by Captain J. P. Basevi, on the recommendation of General Sabine and the Council of the Royal Society, with two pendulums, one of which the General had swung in his notable operations which extend from a little below the equator to within 10° of the pole. Captain Basevi had nearly completed the operations in India, and had taken swings at a number of the stations of the Great Arc and at various other points near mountain ranges and coast lines, when he died of exposure in 1871 at a station on the high table lands of the Himalayas, while investigating the force of gravity under mountain ranges. Major Heaviside swung the pendulums at the remaining Indian stations, then at Aden and Ismailia on the way back to England, and finally at the base station, the Kew Observatory. Afterwards they and a third pendulum were swung at Kew and Greenwich by Lieutenant-Colonel Herschel, who took all three to America, swung them at Washington, and then handed them over to officers of the United States Coast Survey, by whom they have been swung at San Francisco, Auckland, Sydney, Singapore, and in Japan.

The pendulum operations in India have been successful in removing from the geodetic operations the reproach which had latterly been cast on them, that their value has become much diminished since the discovery that the attraction of the Himalayan mountains is so much greater than had previously been suspected, that it may have materially deflected the plumb-line at a large number of the astronomical stations of the Great Arc, and injuriously influenced the observations. Everest considered the effects of the Himalayan attraction to be immaterial at any distance exceeding sixty miles from the foot of the mountains; but in his days the full extent and elevation of the mountain masses was unknown, and their magnitude was greatly underestimated. Afterwards, when the magnitude became better known, Archdeacon Pratt of Calcutta, a mathematician of great eminence, calculated that they would materially attract the plumb-line at points many hundred miles

distant; he also found that everywhere between the Himalayas and the ocean, the excess of density of the land of the continent as compared with the water of the ocean would combine with the Himalayan attraction and increase the deflection of the plumb-line northwards, towards the great mountain ranges, and that under the joint influence of the Himalayas and the ocean the level of the sea at Kurrachee would be raised 560 feet above the level at Cape Comorin.

But as a matter of fact the Indian arc gave a value of the earth's ellipticity which agreed sufficiently closely with the values derived from the arcs measured in all other quarters of the globe, to show that it could not have been largely distorted by deflections of the plumb-line; thus it appeared that whereas Everest might have slightly underestimated the Himalayan attraction, Pratt must have greatly over-estimated it. His calculations were however based on reliable data, and were indubitably correct. For some time the contradiction remained unexplained, but eventually Sir George Airy put forward the hypothesis that the influence of the Himalayan masses must be counteracted by some compensatory disposition of the matter of the earth's crust immediately below them, and in which they are rooted; he suggested that the bases of the mountains had sunk to some depth into a fluid lava which he conceived to exist below the earth's crust, and that the sinking had caused a displacement of dense matter by lighter matter below, which would tend to compensate for the excess of matter above. Now Pratt's calculations had reference only to the visible mountain and oceanic masses, and their attractive influences—the former positive, the latter negative—in a horizontal direction; he had no data for investigating the density of the crust of the earth below either the mountains on the one hand, or the bed of the ocean on the other. The pendulum observations furnished the first direct measures of the vertical force of gravity in different localities which were obtained, and these measures revealed two broad facts regarding the disposition of the invisible matter below; first, that the force of gravity diminishes as the mountains are approached, and is very much less on the summit of the highly elevated Himalayan table lands than can be accounted for otherwise than by a deficiency of matter below; secondly, that it increases as the ocean is approached, and is greater on islands than can be accounted for otherwise than by an excess of matter below. Assuming gravity to be normal on the coast lines, the mean observed increase at the island stations was such as to cause a seconds' pendulum to gain three seconds daily, and the mean observed decrease in the interior of the Continent would have caused the pendulum to lose $2\frac{1}{2}$ seconds daily at stations averaging 1,200 feet above the sea level, 5 seconds at 3,800 feet, and about 22 seconds at 15,400 feet—the highest elevation reached—in excess of the normal loss of rate due to height above the sea.

Pratt was strongly opposed to the hypothesis of a substratum, or magma, of fluid igneous rock beneath the mountains; he assumed the earth to be solid throughout, and regarded the mountains as an expansion of the invisible matter below, which thus becomes attenuated and lighter than it is under regions of less elevation, and more particularly in the depressions and contractions below the bed of the ocean. And certainly we seem to have more reason to conclude that the mountains emanate from the subjacent matter of the earth's crust than that they are as wholly independent of it as if they were formed of stuff shot from passing meteors and asteroids; any severance of continuity and association between the visible above and the invisible below appears, on the face of it, to be decidedly improbable.

The hypothesis of sub-continental attenuation and sub-oceanic condensation of matter is supported by the two arcs of longitude on the parallels of Madras and Bombay; for at the extreme points of these arcs, which are situated on the opposite coast lines, the horizontal attraction has been found to be not landwards, as might have been anticipated, but seawards, showing that the deficient density of the sea as compared with the land is more than compensated by the greater density of the matter under the ocean than of that under the land.

While on the subject of the constitution of the earth's crust, I may draw attention to the circumstance that the tidal observations which have been carried on at a number of points on the coasts of India, as a part of the operations of the

Survey, tend to show that the earth is solid to its core, and that the geological hypothesis of a fluid interior is untenable. They have been analysed by Professor G. H. Darwin, with a view to the determination of a numerical estimate of the rigidity of the earth, and he has ascertained that whilst there is some evidence of a tidal yielding of the earth's mass, that yielding is certainly small, and the effective rigidity is very considerable, not so great as that of steel as was at first surmised, but sufficient to afford an important confirmation of the justice of Sir William Thomson's conclusion as to the great rigidity.

The Indian pendulum observations have been employed by Colonel Clarke, in combination with those taken in other parts of the globe, to determine the earth's ellipticity. Formerly there was wont to be a material difference between the ellipticities which were respectively derived from pendulum observations and direct geodetic measurements, the former being somewhat greater than $\frac{1}{290}$, the latter somewhat less than $\frac{1}{300}$; but as new and more exact data became available, the values derived from these two essentially independent sources became more and more accordant, and they now nearly agree in the value $\frac{1}{293}$.

As a part of the pendulum operations, a determination of the length of the seconds' pendulum was made at Kew by Major Heaviside, with the pendulum which had been employed for the same purpose by Kater early in the present century, when leading men of science in England believed that in the event of the national standard yard being destroyed or lost, the length might be reproduced at any time with the aid of a reversible pendulum. In consequence of this belief an Act of Parliament was passed in 1824 which defined the relations between the imperial and the seconds' pendulum, the length of the former being to that of the latter—swung in the latitude of London, in a vacuum and at the level of the sea—in the proportion of 36 inches to 39·1393 inches. Thus, while the French took for their unit of length the ten-millionth part of the earth's meridional quadrant, the English took the pendulum swinging seconds in the latitude of London. In case of loss the yard is obviously recoverable more readily and inexpensively by reference to the pendulum than the metre by reference to the quadrant; it is also recoverable with greater accuracy; still the accuracy is not nearly what would now be deemed indispensable for the determination of a national standard of length, and it is now generally admitted that every pendulum has certain latent defects, the influence of which cannot be exactly ascertained; thus the instrument cannot be relied on as a suitable one for determinations of absolute length; but, on the other hand, so long as its condition remains unaltered, it is the most reliable instrument yet discovered for differential determinations of the variations of gravity. In truth, however, the pendulum is a very wearisome instrument to employ even for this purpose, for it has to be swung many days and with constant care and attention to give a single satisfactory determination; thus if such a thing can be invented and perfected as a good differential gravity meter, light and portable, with which satisfactory results can be obtained in a few hours instead of many days, the boon to science will be very great.

The trigonometrical operations fix with extreme accuracy two of the co-ordinates—the latitude and longitude—which define the positions of the principal stations; but the third co-ordinate, the height, is not susceptible of being determined by such operations with anything like the same degree of accuracy, because of the variations of refraction to which rays of light passing through the lower strata of the atmosphere are liable, as the temperature of the surface of the ground changes in the course of the day. In the plains the apparent height of a station ten to twelve miles from the observer has been found to be upwards of 100 feet greater in the cool of the night than in the heat of the day, the refraction being always positive when the lower atmospheric strata are chilled and laden with dew, and negative when they are rarefied by the heat radiated from the surface of the ground. At hill stations the rays of light usually pass high above the surface of the ground, and the diurnal variations of refraction are comparatively immaterial, and very good results are obtained by the expedient of taking the vertical observations between reciprocating stations at the same hour of the day, and as nearly as possible at the time of minimum refraction; but in the plains this expedient does not usually

suffice to give reliable results. The hill ranges of central and those of northern India are separated by a broad belt of plains, which embraces the greater portion of Sind, the Punjab, Rajputana, and the valley of the Ganges, and is crossed by a very large number of the principal chains of triangles, on the lines where the chart shows stretches of comparatively small triangles, which are in most instances of considerable length. Thus it became necessary to run lines of spirit levels over these plains, from sea to sea, to check the trigonometrical heights. The opportunity was taken advantage of to connect all the levels which had been executed for irrigation and other public works, and reduce them to a common datum; and eventually lines of level were carried along the coast and from sea to sea to connect the tidal stations. The aggregate length of the standard lines of level executed up to the present time is nearly 10,000 miles, and an extensive series of charts of the levels derived from other departments of the public service and reduced to the survey datum has already been published.

The survey datum which has been adopted for all heights, whether deduced trigonometrically or by spirit-levelling, is the mean sea level as determined, either for initiation or verification, by tidal observations at several points on the coast lines. At first the observations were restricted to what was necessary for the requirements of the survey, and their duration was limited to a lunar month at each station. In 1872 more exact determinations were called for, to ascertain whether gradual changes in the relative level of land and sea were taking place at the head of the Gulf of Cutch, as had been surmised by the geological surveyors, and observations were taken for over a year at three tidal stations on the coasts of the gulf, to be repeated hereafter when a sufficient period had elapsed to permit of a measurable change of level having taken place. Finally, in 1875, the Government intimated that as 'the great scientific advantages of a systematic record of tidal observations on Indian coasts had been frequently urged and admitted,' such observations should be taken at all the principal ports and at such points on the coast lines as were best suited for investigations of the laws of the tides. In accordance with these instructions, five years' observations have been made at several points, and new stations are taken up as the operations at the first ones are completed.

The initiation of the later and more elaborate operations is due in great measure to the recommendations of the Tidal Committee of the British Association, of which Sir William Thomson was President. The tidal observations have been treated by the method of harmonic analysis advocated by the Committee. The constants for amplitude and epoch are determined for every tidal component, both of long and of short periods, and with their aid tide-tables are now prepared and published annually for each of the principal ports; and further, it is with them that Professor G. H. Darwin made the investigations of the effective rigidity of the earth, which I have already mentioned. The very remarkable waves which were caused by the earthquake on December 31, 1881, in the Bay of Bengal, and by the notable volcanic eruptions in the island of Krakatoa and the Straits of Sunda on August 27 and 28, 1883, were registered at several of the tidal stations, and thus valuable evidence has been furnished of the velocities of both the earth-wave and the ocean-wave which are generated by such disturbances of the ordinarily quiescent condition of the earth's crust.

I must not close this account of the non-graphical, or more purely scientific, operations of the Great Trigonometrical Survey of India without saying something of the officers who were employed thereon, under the successive superintendence of Everest, Waugh, and myself. A considerable majority were military, from all branches of the army—the cavalry and infantry, as well as the corps of engineers and artillery; the remainder were civilians, mostly promoted from the subordinate grades. Prominent shares in the operations were taken by Lieutenant Renny, Bengal Engineers, afterwards well known in this neighbourhood as Colonel Renny Tailyour, of Borrowfield in Forfarshire, of whom and his contemporary, Lieutenant Waugh, Everest, retiring, reported in terms of the highest commendation; by Reginald Walker, of the Bengal Engineers, George Logan, George Shelverton, and Henry Beverley, all of whom fell victims to jungle fever; by Strange, F.R.S., of the Madras Cavalry, whose name is associated with the construction of the

modern geodetic instruments of the Survey; by Jacob—afterwards Government Astronomer at Madras—Rivers, and Haig, all of the Bombay Engineers; Tennant, C.I.E., F.R.S., Bengal Engineers, afterwards Master of the Mint in Calcutta; Montgomerie, F.R.S., of the Bengal Engineers, whose name is best remembered in connection with the Trans-Himalayan geographical operations; James Basevi, of the Bengal Engineers, who so sadly died of exposure while engaged on the pendulum operations in the higher Himalayas; Branfill, of the Bengal Cavalry; Thuillier, Carter, Campbell, Trotter, Heaviside, Rogers, Hill, and Baird, F.R.S., all engineer officers; also Hennessey, C.I.E., F.R.S., M.A., Herschel, F.R.S., and Cole, M.A., whose names are intimately associated with the collateral mathematical investigations and the final reduction of the principal triangulation.

The Trigonometrical Survey owes very much to the liberal and even generous support which it has invariably received from the Supreme Government, with the sanction and approval, first of the Directors of the East India Company, and afterwards of the Secretary of State for India. In times of war and financial embarrassment the scope of the operations has been curtailed, the establishments have been reduced, and some of the military officers sent to join the armies in the field; but whatever the crisis, the operations have never been wholly suspended. Even during the troubles of 1857–58, following the mutiny of the native army, they were carried on in some parts of the country though arrested in others; and the then Viceroy, Lord Canning, on receiving the reports of the progress of the operations during that eventful period, immediately acknowledged them to the Surveyor-General, Colonel Waugh, in a letter from which the following extract is taken:

'I cannot resist telling you at once with how much satisfaction I have seen these papers. It is a pleasure to turn from the troubles and anxieties with which India is still beset, and to find that a gigantic work, of permanent peaceful usefulness, and one which will assuredly take the highest rank as a work of scientific labour and skill, has been steadily and rapidly progressing through all the turmoil of the last two years.'

The operations have been uninfluenced by changes of *personnel* in the administration of the Indian Empire, as Governor-Generals and Viceroys succeeded each other, but have met with uniform and consistent support and encouragement. It may well be doubted whether any similar undertaking, in any other part of the world, has been equally favoured and as munificently maintained.

In conclusion I must state that I have purposely said nothing of the graphical operations executed in the Trigonometrical and other branches of the Survey of India, because they are more generally known, their results appear in maps which speak for themselves, and time would not permit of my attempting to describe them also. They comprise, *first*, the general topography of all India, mostly on the standard scale of 1 inch to the mile; *secondly*, geographical surveys and explorations of regions beyond the British frontier, notably such as are being carried on at the present time on the Russo-Afghan frontier, by Major Holdich and other officers of the Survey; *thirdly*, the so-called Revenue Survey of the British districts in the Bengal Presidency, which is simply a topographical survey on an enlarged scale—4 inches to the mile—showing the boundaries and areas of villages for fiscal requirements; and *fourthly*, the Cadastral Survey of certain of the British districts in the Bengal Presidency, showing fields and the boundaries of all properties, on scales of 16 to 32 inches to the mile. There are also certain large scale surveys of portions of British districts in the Madras and Bombay Presidencies, which, though undertaken originally for purely fiscal purposes by revenue and settlement officers working independently of the professional survey, have latterly been required to contribute their quota to the general topography of the country. And of late years a survey branch has been added to the Forest Department, to provide it with working maps constructed for its own requirements on a larger scale than the standard topographical scale, but on a trigonometrical basis, and in co-operation with the Survey Department. But this brief capitulation gives no sort of idea of the vast amount of valuable topographical and other work for the requirements of the local Administrations and the public at

large—always toilsome, often perilous—which has been accomplished, quite apart from and in quantity far exceeding the non-graphical and more purely scientific work which I have been describing. Its magnitude and variety are such that a mere list of the officers who have taken prominent shares in it, from first to last, would be too long to read to you. Three names, however, I must mention: *first*, that of General Sir Henry Thuillier, who became Surveyor-General on the same day that I succeeded to the superintendence of the Great Trigonometrical Survey, and with whom I had the honour of co-operating for many years; under his administration a much larger amount of topography was executed than under any of his predecessors, and a great impetus was given to the lithographic, photographic, engraving and other offices in which the maps of the survey are published; *secondly*, that of Colonel Sconce, who became Deputy Surveyor-General soon after my accession in 1878 to the Surveyor-Generalship, and with whom I was associated for some years, much to my gratification and advantage, in various matters, but more particularly in the establishment of cadastral surveys on a professional basis at a moderate cost, to render them more generally feasible, which was a matter of the utmost importance for the administration of the more highly populated portions of the British provinces; and *thirdly*, that of Lieutenant-Colonel Waterhouse, who has for many years superintended the offices in which photography is employed, in combination with zincography and lithography, for the speedy reproduction *en masse* of the maps of the Survey, and has done much to develop the art of photogravure, whereby drawings in brushwork and mezzotint may be reproduced with a degree of excellence rivalling the best copperplate engraving, and almost as speedily and cheaply as drawings in pen and ink work are reproduced by photozincography.

Mr. Clements Markham's Memoir on the Indian Surveys gives the best account yet published of the several graphical surveys up to the year 1878. In that year the Trigonometrical, the Topographical, and the Revenue branches, which up to that time had constituted three separate and almost independent departments, were amalgamated together into what is now officially designated 'the Survey of India.' In the same year the chronicle so well commenced by Mr. Markham came to an end on his retirement from the India office—unfortunately, for it is a work of excellence in object and in execution, and most encouraging to Indian surveyors, who find their labours recorded in it with intelligent appreciation and kindly recognition.

During the present meeting, several papers by officers of the Survey will be read —one by Colonel Barron, in person, on the cadastral surveys in the organization of which he has taken a leading share; by Major Baird, on the work of the spirit-levelling which he superintends conjointly with the tidal observations; by Colonel Godwin-Austen, on Lieutenant-Colonel Woodthorpe's recent journey from Upper Assam to the Irawadi river; by Colonel Branfill, on the physical geography of Southern India; and by Colonel Tanner, on portions of the Himalayas and on recent explorations in Southern Tibet. Major Bailey will also read a paper on the forest surveys.

The following Papers were read:—

1. *The Indian Forest Survey.* *By* Major F. Bailey, *R.E., F.R.G.S.*

It is only in comparatively recent times that measures have been undertaken to preserve what remained of the great Indian forests. The first thing to do was to demarcate the tracts which were to be reserved and to free them as far as possible from rights. The area now reserved is about 48,000 square miles, or about $5\frac{1}{2}$ per cent. of the total area of British India, not including the native states. The tracts demarcated owe their immunity from destruction either to the fact that they occupy ground which was, in the absence of communications, inaccessible, or which is much broken, or cannot be irrigated. They are situated either in the plains or on the low ranges of hills rising from them, or on the lower or middle

slopes of the Himalayas up to an elevation of 8,000 or 9,000 feet above sea level. Although they include within their boundaries considerable areas which have been wholly or partially denuded of trees, the ground is generally speaking more or less densely covered with trees and jungle.

In former years accurate forest maps were not required, but the present system of management renders good maps indispensable, and in 1872 measures were taken to provide them. The Imperial Survey Department could not conveniently undertake the work, and it was consequently thought desirable to organise a special branch of the Forest Department to act under the control of the Surveyor-General. This arrangement has worked most satisfactorily. The scale of the maps formed the subject of much discussion, but ultimately it was decided that the scale should usually be 4″ = 1 mile for the most valuable forests, and 2″ = 1 mile for those of less value. An establishment of surveyors was then raised and trained. The first work undertaken was the survey of the forests of Dehra Dun, area about 573 square miles, the non-forest lands of the district being surveyed at the same time by the Imperial Survey Department, and a combined map of the whole country being thus produced. The next work was the survey of the Kumaon and Garhwál forests, area about 1,400 square miles; and the survey of an area of about 1,600 square miles in Haiderabad is now in progress. Altogether since 1872 about 3,000 square miles have been surveyed and mapped, mostly on the scale of 4″ = 1 mile. It will of course take a long time to work over the whole of the forest property, but detailed maps of the entire area are not urgently needed at the present time, since for forests in which simple protection can alone be attempted small-scale maps or sketch maps will suffice for some years to come.

When the survey party takes the field, the officer in charge has command of a considerable number of men, with a large quantity of stores and equipment. He has to hire carts or camels, and march to the scene of the work. On arrival, each native surveyor is given a piece of work, four or five of them being grouped under one European surveyor, and a computing office is established in some central position. When sufficient work of this kind has been done, or when the season is too far advanced for it to be continued, the party moves back to head-quarters. If such work is not well controlled it is sure to show this in inferior quality, insufficient quantity, or high cost. The procedure must be varied according to circumstances, and it has to be considered how a map that will answer the purpose can be produced in the shortest time and at the smallest cost. The ground worked over by the Forest Survey Department presents exceptional difficulties, of which the following are the principal: the surface is much broken up, the crop of trees and jungle is dense, the supply of drinking water is precarious and often of bad quality, the forests are infested with wild animals, food is difficult to obtain, and jungle fever is by no means uncommon. The wild animals are not at all appreciated by the unarmed native surveyors, and many cases have occurred in which they have caused the most serious inconvenience, stopping the survey of certain tracts for a long time. The experience gained of the natives of India in the Forest Survey Department has shown that almost anything can be made of them. The principle adopted has been to stimulate them to exertion and to promote a spirit of emulation among them; they were taught that accuracy was of more importance than rapidity, and encouraged to bring to notice all discrepancies in their work. At first only the most simple operations were entrusted to natives, but a few of them can now do excellent work of the most difficult kind. The combination of European and native labour has answered very well. Detailed surveys of wild and densely wooded ground have rarely been made before in India, and it is evident that they must be more expensive than similar surveys of open, cultivated country; but to provide them is a necessity and a distinct economy.

2. *Account of the Levelling Operations of the Great Trigonometrical Survey of India. By* Major A. W. Baird, *R.E., F.R.S.*

From the origin of the Great Trigonometrical Survey of India until the year 1858 all determinations of relative height were effected by the measurement of reciprocal vertical angles, a method which is based on the assumption that the back and forward angles are equally refracted, in which case the difference of height deduced from them should be exact. But when rays of light passing between two mutually observing stations traverse the lower strata of the atmosphere and graze the surface of the ground, the refraction is rarely identical at both stations even at the same moment of time, and is liable to vary greatly at different hours of the day and at the same hour on different days. Thus determinations of the relative height of stations situated on extensive plains by this method are liable to considerable inaccuracies; and as a belt of plains of great extent—in places several hundred miles broad—intervenes between the hill ranges of Lower and Central India and those of Upper India, and every principal chain of triangles has had to be taken over these plains for a greater or less distance, lines of spirit-levels were initiated, to be carried across them from sea to sea, as a check on the trigonometrical determinations of height. The opportunity was availed of to connect and reduce to a common datum the levels executed in all parts of India for irrigation, railway, and other purposes. Subsequently, when systematic tidal observations came to be undertaken at various points on the coast, lines of level were carried between the tidal stations, to serve as a check on the spirit levelling, and also to connect the tidal stations together.

Every line is gone over by two surveyors working independently of each other, with separate instruments and staves, and comparing results from time to time. The staves have two faces, both graduated in feet and tenths, but one with black divisions on a white ground reading from 0 to 10, the other with white divisions on a black ground reading from 5·55 to 15·55, which gives a useful check against accidental gross errors of reading, as the observer has no bias to repeat on the second face an error made in reading the first. The bulbs of the levels are fitted with graduated scales; the readings of the ends of the bubble are recorded, and corrections are applied for dislevelment, as with astronomical instruments. As there is a tendency to an accumulation of minute constant error in all levelling operations, such tendency is guarded against as far as practicable by alternating the order of the back and forward staff readings at successive stations, and also alternating the direction of operation on successive days or in successive sections of each line.

The rate of progress is not, of course, as rapid as in levelling operations executed with less care and precision, but an average of four miles daily may generally be relied on. Up to the present time 9,680 miles of rigorously executed double line have been completed, and about 300 miles of single line to connect collateral and subsidiary bench marks.

The first five lines which were executed to connect tidal stations indicated, in every instance, that the sea level was apparently higher at the southern than at the northern station. It is quite possible that the level of the surface of the sea may be disturbed under the influence of local attractions, and be higher at some points of a coast-line than at others; but the actual difference of level is only ascertainable approximatively by calculations based on various assumptions regarding the constitution of the earth's crust and the surrounding elements of attraction. It cannot be measured, because the attractions have the same influence on the fluid in the bulbs of the levelling instruments as on the waters of the ocean, when both are equally exposed to their influence; thus, when working along a line of *open* coast the instrumental would coincide with the ocean level, and a large deviation from the normal level of the ocean might exist without any possibility of measuring it. Thus it seemed that the apparent raising of the southern ends of these lines of level must be due not to actual variations in the height of the mean sea, but to some error in the levelling operations. They had been conducted with scrupulous care, and with every conceivable precaution to guard against either accidental gross

error or systematic accumulation of minute constant error; yet a source of minute but cumulative error remained which, coming from an external quarter, was not guarded against by alternating the direction of operation or by any of the expedients adopted for eliminating inherent cumulative errors. It lay in the admitted tendency there is, when levelling an instrument, to unduly depress the telescope in the direction of the light which illuminates the spirit-level of the instrument, thus making all objects viewed through the telescope, when pointed in that direction, appear too high. The sun was the invariable source of illumination, and it was always to the south of the observer, and therefore the southern ends of the lines of levels would have a tendency to be brought out too high. This illumination error is a maximum on the meridian and vanishes on the prime vertical; however great its magnitude, it re-enters and is non-apparent in a circuit of levels; it would only be apparent on lines starting and closing at different points on the mean sea, which gives an independent check on the accuracy of the line of levels. It is a *vera causa* of error such as has actually been met with; but there is now some reason to doubt whether it really was the cause, for the two lines next measured from sea to sea brought the northern ends out highest, and a third line recently completed shows no appreciable difference between the north and south ends. The later results may, however, be due to the observers having been more careful to guard against illumination error. In seven lines out of the eight the discrepancies are small, not exceeding two inches in 100 miles of line; but there is one large discrepancy of $4\frac{3}{4}$ inches per 100 miles, accumulating to 3 ft., on the line between Bombay and Madras. The two weakest sections of this line have been re-levelled, but in each instance with results which were identical with those first obtained. If the observations are errorless in themselves, error must have been introduced by the local attractions encountered on the line which crosses the western ghats and the elevated plateau lying between Bombay and Madras. These attractions would obviously influence the levels of the contiguous instruments in a greater degree than the distant waters of the ocean.

---

3. *Notes on the Physiography of Southern India.*[1]
By Colonel B. R. Branfill.

The part of India to which these notes are confined lies to the south of latitude 15°, and mostly in the Madras Presidency. Its principal characteristics are great diversity of feature and mildness of climate, which, though tropical, is almost insular, and entirely subject to the effects of the south-west and the north-east monsoons. It is a region of mountains and hills, elevated table-lands and low-lying flats, fertile plains and barren wastes, flooding rivers with beautiful waterfalls and innumerable artificial lakes, tropical forest, endless groves, and jungly wilderness.

Southern India is an interesting field of observation for the naturalist, and particularly for the physiographer, on account of the elements of change in active operation:—firstly, the decomposing and disintegrating power of the sun's rays, vertical twice every year; secondly, the long-continued violent winds that scour the surface and transport immense volumes of matter to great distances in the air, and, by means of the ocean waves, along the shore; thirdly, the torrents of rain that denude the hill surfaces and score the slopes with deep channels, depositing the spoil on the flooded flats, the growing deltas, and the shoaling shore.

Many other elements of change are at work, and the earthquake alone seems wanting. These agencies seem fully adequate to the task of converting a vast plateau of igneous matter, overlying a granitic base, into the subdued and diversified area we now behold.

For the purpose of these notes the author divides Southern India into three tracts. First, the mountainous region of the Gháts, including the higher tablelands and the great upland plains of Maisúr contained between the Western and Eastern Gháts. Second, the lowlands of the Malabar coast: all that narrow tract of moist sea-board between the foot of the Western Gháts and the Arabian Sea.

[1] Printed in the *Proceedings of the Royal Geographical Society* for November, 1885.

Third, the comparatively dry lowland plains of the Carnatic between the Ghâts and the Bay of Bengal.

The year, for Southern India, is also divided into three seasons: the south-west monsoon, from May to September; the north-east monsoon, from October to February; and the hot season of March, April, and May, between the two monsoons.

The south-west monsoon is shown to be the most important fact and factor of the climate of Southern India. The wind blows very strongly for four months over the Arabian Sea from the south-west. On nearing the coast of Southern India it becomes more of a westerly wind, and retains this direction across the country to the Bay of Bengal. When it strikes the west coast and mounts the barrier wall of the Western Ghâts it drops most of its moisture in torrents of rain, by which the eastward-flowing rivers are flooded as well as the lowlands of Malabar. On the table-lands east of the Ghâts it is strong, cool, and showery, but gradually becomes drier and warmer, and reaches the Coromandel coast as a dry and hot land wind—a veritable *sirocco.* In the Bay of Bengal it regains its northward course, and the cause of its deflection therefrom in crossing Southern India is not quite clear. After a short interval the north-east wind sets in, usually bringing with it some heavy spells of rainy weather, and lasts with little interruption till February. The whole of the country east of the Western Ghâts benefits from these rains, which fill the rivers and reservoirs and moisten the unirrigated tracts sufficiently to enable what is called the cold-weather crop to be grown. The hot season sets in in March, rapidly increasing in intensity till the return of the south-west monsoon. It is tempered, however, by the sea breezes, which are felt far inland. The most agreeable time for visiting India is from October to March; but the naturalist, the physiographer, and the scientific observer need not be deterred by the fear of any danger incidental to a prolonged tour in Southern India, as, by taking advantage of the great variety and agreeable nature of the climates afforded by the high plateaux and hill ranges, the whole year may be spent in a comparatively cool, healthy, and enjoyable climate.

The author suggests a tour which embraces some of the most noteworthy features in the south of India.

Proceeding by sea to Kárwár, near Goa, note about the only sheltered harbour for ships south of Bombay, favourably situated opposite a gap in the W. Ghâts. Landing at Honáwar, observe its fine tidal estuary and the extraordinary surf formed on the bar at the ebb of spring tides. Now ascend the *ghát*, or pass, near here, and visit the splendid Gersappa Falls, where the river Sharávati leaps down at one bound over a sheer precipice 800 feet, in the midst of magnificent wooded mountain scenery. Observe that the Western Ghâts are very steep or precipitous on their western face only, and can hardly be called a range of mountains, but are rather a line of buttresses to the Maisúr highland plateau. The word *ghát* simply signifies a pass or passage, and amongst the natives of India is restricted to that meaning. Proceeding eastwards, visit the high undulating plains of Maisúr, called in the neighbourhood of the Ghâts *Malnád,* or hill country. Bednor, in the Nagar Malnád, the former capital of the local chieftain, a place in ruins now, and almost deserted, is worth a visit to see how soon a town of 100,000 houses and perhaps half a million of inhabitants can be obliterated. After a glance at Maisúr and the Kábéri Falls, the port of Mangalore is visited, to study the shifting of the river mouth and other points of interest, the return to the high lands being made by the next pass up into Kurg (*Coorg*), which for the beauty of its highland scenery and general interest may compare with any such district in the world.

Continuing southwards, the next highland district along the brow of the Ghâts is Wainád, somewhat similar to the Malnád, but not so mountainous as Kurg. It is notable for the British coffee planting industry and the recent gold-mining enterprise.

Thus far the highland districts mentioned are part and parcel of the great central plateau contained between the Western and the Eastern Ghâts. Their general level varies from 2,500 to 3,500 feet above sea, with isolated peaks and masses running up to 5,000 and 6,000 feet. Next comes the Nílgiri plateau, nearly isolated

from the Wainád, at a general altitude of 5,000 to 6,000 feet, and with summits running up to 8,000 feet and upwards. Its undulating grassy surface, splendid climate and scenery are noticed.

The tour is continued to the south of the Nílgiri Mountains, where the high wall of the Western Gháts abruptly terminates, giving place to a wide low passage called the Pálghát Gap, to the south of which the mountains rise again to their full height, and are often termed generally the Southern Gháts. They are more like a true mountain range, springing directly from the low country on all sides. They are not known to contain any large table-land or plateau on their summits, but are broken up into large valleys and lofty peaks, the highest point (Aneimudi), which is also the highest in India south of the Himálaya, attaining 8,838 feet.

Thence the author takes us to the Palani Hills, a peninsular hilly plateau in two steps, somewhat resembling the Nílgiri plateau and the Wainád, then down to the eastern plains with their remarkable red sand-hills drifting like waves before the wind; then south to Cape Comorin, the land's end, and finally round by way of the east coast and Rameswaram to Trichinopoly.

4. *On a Trip from Upper Assam into the Kampti Country and the Western Branch of the Irrawady River, made by Colonel R. B. Woodthorpe, R.E., and Major C. R. MacGregor. By* Lieut.-Colonel H. H. GODWIN-AUSTEN, *F.R.S.*

Colonel Woodthorpe's recommendation to the Chief Commissioner of Assam to take up again the exploration of the mountainous country in Eastern Assam, and to penetrate if possible beyond the water-parting, having been acceded to by the Indian Government, survey operations were commenced last winter in the valley of the Diúng, or upper waters of the Noa Dihing of the plain country. While engaged on this work, Colonel Woodthorpe, accompanied by Major MacGregor and Messrs. Ogle, Grant, and Latouche, reached the pass of Chanken, 8,300 feet, at the head of the valley, and it was then decided that an effort should be made to visit the Kampti villages on that branch of the Irrawady visited by Wilcox sixty years ago, and never attempted since. It was impossible that the whole party could go, so the three last named returned to finish the survey of the Diúng Valley, while Colonel Woodthorpe and Major MacGregor, who commanded the escort, went on alone. They travelled lightly, with only four sepoys and forty coolies, and in extremely inclement weather, after six days, reached the stockaded village of Langnú, and were well received. They then went on as far as the right bank of the Nam Kiu River, a large tributary of the Irrawady, rising in the snowy range to the northward; it was here eighty yards wide, with long deep pools and rapids. Thence going on to Padao, they saw the chief Rajah, Lukún, of the district, who came from his summer residence to meet them, and he was most friendly, and begged them to stay a month and see all the country. The approaching rainy season rendered this impossible, and they had to start back at once for the Assam side, only doing so just in time, the swollen rivers being far more difficult to cross than on the outward journey. The whole expedition was well planned and carried out, and if the same tact and judgment can be shown in our future relations with these Kamptis, we shall soon know as much of the country on the head waters of the Irrawady as we do now of the Garo, Khasi, and Naga Hills.

Only a very ordinary road is required, crossing some point on the Patkai range, to open up a future trade with these people from the Assam side. And to this may be added the knowledge of the geology, the zoology, and botany of this most interesting region.

7. *Notes on recent Mountaineering in the Himalaya.*
By DOUGLAS W. FRESHFIELD, *F.R.G.S.*

SATURDAY, SEPTEMBER 12.

The Section did not meet.

MONDAY, SEPTEMBER 14.

The following Papers and Reports were read:—

1. *Projected Restoration of the Reian Mœris, and the Province, Lake, and Canals ascribed to the Patriarch Joseph.* *By* COPE WHITEHOUSE, *M.A.*

The Berlin Geographical Society has published, in its *Zeitschrift* for May 1885 (No. 116), the latest map of Egypt, from the Fayoum to Behnesa, and from the Nile to the Little Oasis. The text by Dr. Ascherson gives credit for a considerable area to the topographical observations presented to this society at Montreal. So much of the Reian basin as lies between the Qasr Qerūn and the Qasr Reian has not been visited by any European except the author of this paper (1882, 1883). It is now an accepted fact that there is a depression south of the Fayoum, not less than 150 feet below the level of the Mediterranean, with a superficial area at the level of high Nile of several hundred square miles. It is irregular in shape, curving like a horn from a point near Behnesa to the ridge which separates it from the Fayoum. In the southern part are two, and perhaps three, patches of vegetation, wild palm-trees, and ruins of Roman and early Christian date. This part was visited by Belzoni, May 22, 1819; Calliaud, November 24, 1819; Pacho and Müller, 1823–24; Sir G. Wilkinson, 1825; Mason Bey, 1870; and Ascherson, March 27, 1876. Dr. Ascherson determined by aneroid observations that his camp was 29 metres below the sea. Calliaud found ruins about +38 m., or about the level of high Nile in the valley on the same latitude. The aneroid, theodolite, and other observations of March 6 and April 4, 1882, and April 1883, by the author of this paper, established a depth of −175 to −180 English feet. The greatest depth is probably under the western cliffs south of the Haram Medhūret el-Beṛl. No previous explorer had conceived it possible that this might have been a lake within historic times. The level of the ruins, as determined by Calliaud, shows that the ancient station of Ptolemais might have been, as represented in the text and maps of Claudius Ptolemy, on a horn-shaped lake about thirty-five miles long and fifteen wide, with a maximum depth of 300 feet, fed by a canal, partly subterranean, from Behnesa, as well as by a branch of the present Bahr Jūsuf communicating with it through the Fayoum. The lower plain of the Fayoum had been, at that time, fully redeemed, and the present Lake of the Horn reduced to such insignificant dimensions as to be unnoticed. The restoration of the Reian basin of Lake Mœris and the drainage by evaporation of the Birket el-Qerūn would be a repetition in modern times of the best results reached in the Greco-Roman period, perhaps 3,000 years after the first effort to utilise these two unique basins for storage and drainage.

The feasibility of the scheme is partly based upon the Mohammedan traditions in regard to the original redemption of the Fayoum, the construction of the existing canals, and the reservoir of water which formerly filled the Wadi Reian. It had been stated by Sir G. Wilkinson that the Bahr Jūsuf, or Canal of Joseph, owed its name to a restoration under Saladin (*ca.* A.D. 1166). Masūdi (born, Bagdad,

A.D. 885; died, Cairo, A.D. 956) gives in chapter xxi. one of the very numerous forms of the tales in which the principal engineering works of Middle Egypt are assigned to the patriarch Joseph. Joseph also seems to be the Souphis of the Greeks.

It is a question for consideration whether the descriptions of Goshen and the region occupied outside of Goshen proper, and known as the land of Raamses, apply to this part of Middle Egypt. In a posthumous treatise of great critical value, Jablonski of Frankfort (1693–1767) asserted that in Egypt from all time men have been of the opinion that the Israelites dwelt in the present provinces of Beni-Suef and el-Fayoum. Important finds of papyri, and the publication by the Dutch Academy of Sciences of a geographical papyrus of Mœris (of late date, exhibited), its towns and canals, and the Labyrinth, have stimulated the imagination of the archæologist and the historian to a high pitch. The representation of a stately array of cities with emblazoned arms, of fish, aquatic birds, and pasturages for cattle on the western shore, further serves to justify the peculiar admiration expressed for this region by Greek and Roman travellers, as well as by the Semitic historians. The Ionians, Sicilians, and Romans willingly conceded that its public works, in three categories, transcended in splendour and in usefulness the most stupendous efforts elsewhere extant. Their origin was virtually unknown. They were apparently not Egyptian. The Hyk-Sos or Lords of ta-She seem to have been Arabians, who seized upon the strategic advantages of the Fayoum and (in the words of the Nubian geographer, applied to a somewhat similar work in Arabia), made this reservoir not only for the use of the inhabitants, but to keep the indigenous population in greater awe by being masters of the water. Like the Moors in Southern Spain, their works gradually deteriorated in alien hands, and are now, after 4,000 years, at their lowest point. The work of restoration is comparatively easy. The following advantages would result:—First, the lake and morass, now increasing, in the Fayoum would be diminished, and a large amount of land redeemed; second, the danger of an excessive rise of the Nile would be averted, and the labour of taking precautions against it saved; third, a considerable amount of abandoned land, now desert, would be irrigated; fourth, an immense reservoir would deliver water at a high level for navigation as well as irrigation, and even power; fifth, Lakes Menzaleh, Bourlos, Edkou, and Mareotis could be reclaimed, and those parts of the Delta would then again resemble the shores of Holland and the mouths of the Rhine.

2. *Report of the Committee for furthering the Scientific Examination of the Country in the vicinity of Mount Roraima in Guiana.*—See Reports, p. 690.

3. *Mount Roraima.* *By* EVERARD IM THURN.

4. *Report of the Committee appointed for the purpose of promoting the Survey of Palestine.*—See Reports, p. 691.

5. *The Cadastral Survey of India.* *By* Lieut.-Colonel W. BARRON.

The surveyor in India works under various conditions as regards climate and country, and prepares his maps on different scales, to suit the purposes for which the survey is intended.

The Cadastral Survey of India is ordinarily on the scale of 16 inches to a mile, though sometimes on a much longer scale; it has been undertaken to enable the Government to assess the land revenue, and to define the rights of landlords and tenants. About 22½ millions of land revenue is collected yearly, and is assessed in different ways, under both permanent and temporary settlements.

Former field maps were either eye-sketches, or were surveyed with varying degrees of accuracy by non-professional agency, acting under settlement officers,

and the professional survey surveyed the village lands topographically, and determined the exact area of the village as a check on the settlement areas. In 1871 the settlement surveys in the North-West Provinces were made over to the professional surveyors, and since that time various modifications and improvements have been introduced, with the result that the Survey now prepares all the papers and statistics required by the Settlement Department for assessment.

Based on points whose data have been calculated by the Great Trigonometrical Survey of India, the surveyor fixes other points on the boundaries of the villages of a district, and from these again he works down to each individual field, which is the unit of survey. The areas of each village and of each field are calculated, and all the processes are checked and proved throughout.

The proprietary and cultivating tenures are very complicated, and the land is very much cut up by subdivision among the landlords and tenants. The Survey prepares 'records of rights' and 'rent-rolls,' defining the rights and giving the castes of landlords and tenants for each field. It also collects information regarding the rents paid, the crops grown, the nature of the soil, and the means of irrigation, and prepares abstracts of these to guide the settlement officer in his assessments.

The village maps are reproduced by photography, and are also reduced to smaller scales to make up district maps and the atlas of India.

The establishment of a Cadastral Survey during the field season is very large; it is reduced to an office establishment during the hot weather. The yearly outturn ranges from 650 to 800 square miles, comprising sometimes over a million of fields.

Great advantages are derived from the Cadastral Survey, such as stopping litigation about boundaries of villages and fields, defining the rights of landlords and tenants, enabling the Government to know the amount of land under cultivation, and to provide for famines and for the social problems that will be developed in the near future by the great increase of population.

7. *The Rivers of the Punjab.* *By* General ROBERT MACLAGAN, *R.E.*

The country called Punjab receives its name from the rivers which give it its distinctive geographical character. The name, as is well known, means 'five waters,' and they are the five great tributaries of the Indus, namely, Jhelam, Chináb, Rávi, Biás, and Satlaj.

In early times it was called the land of the *seven* rivers, including the Indus itself on one side, and on the other the Saraswati, which was the eastern boundary of the land occupied by the Aryan immigrants from the north (about 1500 B.C.).

The modern British province which we call Punjab—the country marked off for administrative purposes as the charge of the local government—is not thus bounded by the lines of one river system. It includes on one side the strip of country between the Indus and the hills, and on the other a large extent of cultivated plain as far as the Jamna, a river which has different geographical relations.

The seven-river-land (Sapta-Sindu) of the early Aryans had distinct river boundaries, as then understood. The Saraswati, its eastern boundary, presents to us an interesting geographical problem. It is not now such a river as is described in the ancient writings, in which it is mentioned along with the others, and as being of still greater size and importance. Nor can it ever have been a river of the same kind, as it has its source in the low outer hills, while the others come from perpetual snows. Its channel is dry for great part of the year, and it never carries water on so far as to unite with the other rivers. The changes in the country through which it passes may account for a great change of the river. About the sixth century B.C. the Saraswati is said to sink into the earth, and to pass underground to join the Ganges and Jumna at their confluence. This seems intended to describe a river such as it is now.

As a solution of the problem it has been supposed that the Satlaj, instead of turning west at Rúpar and joining the Biás, once ran S.W. by the course of the Saraswati, and that this is the ancient river referred to in the Vedic hymns. It is not impossible that the Satlaj may have once taken this course, but it does not appear that this view can be supported as explaining the difficulty regarding the Saraswati. It is as likely that this river was described in early days on imperfect knowledge of it, perhaps on some occasions when it was seen in flood, and that when the people had advanced beyond it and had become more fully acquainted with it, it was described more appropriately in the later tradition above mentioned.

The Satlaj, whether flowing as at present or by the line of the Saraswati, is the distinct eastern boundary of a great area of hill and plain country enclosed between it and the Indus. These two rivers have their sources within a short distance of each other, on the opposite sides of the same mountain mass, and they unite in the south of the Punjab, the Indus having run a course of about 1,350 miles and the Satlaj about 950. The maximum distance between them, the breadth of the area they enclose, is about 350 miles. The other four rivers are within this ring formed by the Indus and the Satlaj. All of them have certain characters in common, and each certain distinguishing features of its own. Their course among the hills is more or less similar, the Jhelam presenting one special difference; and their hill course, being for the most part in channels with permanent rocky banks and beds, varies little from year to year. In the lower and slower part of their course also they are generally similar, and, like all rivers travelling through alluvial plains, are subject to changes.

These alterations are of two kinds—constructive and destructive. They cut down their banks and they build others. The destruction of high banks is, in floods, by the force of the stream in direct attack, and in the low season by quiet undercutting at the water-level. The matter thus carried off is laid down again, either on the low banks on the opposite side, or in the river, raising shoals and islands, or across the mouths of branch channels, blocking them up and laying them dry. All this is familiar to people in other parts of India and in other countries where great rivers traverse similar plains. There are long stretches of the Mississippi banks which exactly resemble those of the Indus, and which the river treats in exactly the same way. Something can be done, and is done when necessary, to check the erratic movements of rivers endangering property of value. Protective and directing works have at different times been carried out on the Indus, the Rávi, and the Satlaj. Besides changes of channel and destruction of banks when a main stream takes to oblique courses, a river keeping a straight course is liable in flood to cut deep furrows in its bed. Thus the Satlaj a few years ago brought down one pier of the railway bridge, sunk to a depth of 70 feet, by scooping out the bed below it.

The changes of river channels and of the direction of the main stream are unfavourable to navigation. In the Punjab steam navigation has practically been discontinued on all the rivers except the largest, namely, the lower Indus, and the combined Jhelam, Chináb, and Rávi, up to Multan. River conservancy, in the sense of works for keeping open certain channels for navigation, is too costly for application on a large scale. It is found better, where steam navigation is kept up, to maintain local pilotage. Though they are not well suited for steam navigation, there is extensive boat traffic on the Punjab rivers. And on the Jhelam and Chináb, near the foot of the hills from which the pine timber comes, there is constant boatbuilding for the lower Indus.

In 1841, and again in 1858, there were very striking and serious floods in the Indus, caused by temporary obstruction of narrow gorges in the hills. In both cases warning came (but was not fully understood) by the river at Attak falling when it should have been rising. The effect, when the barrier gave way, was very remarkable and very destructive. In 1858 the Kabul River was driven back by the immense volume and force of the released Indus, which flowed up stream as far as the British station of Naoshera, which was inundated and destroyed.

The Indus, when it reaches the plains, has a temperature in winter about 5° below that of the air. The difference in summer, when the river is being fed by

melting snows, is about 14°. At a great depth the difference is greater, a circumstance which is turned to practical use at Attak.

The fall of these rivers being greatest in the hill portion of their course, and decreasing as they come down through the plains, the vertical section of their course is a curve terminating in a nearly horizontal line at the sea. From Attak to Kalabagh the fall of the Indus is 50 inches per mile, from Kalabagh to Mittan Kote 12, and from Mittan Kote to the sea 6, the end part being less. The result is a constantly increasing tendency to deposit silt and raise the bed, and by overflow to raise the banks. For a great part of its course the Indus flows in a channel slightly above the level of the land on either side.

The local rainfall of the country through which these rivers flow in the Punjab diminishes gradually in quantity from their first entrance on the plains to the place of their junction above Mittan Kote. The Chináb issues from the hills in a region of 51 inches annual rain, the Indus and the Jhelam 36, the Rávi and the Biás 53, the Satlaj 26; and their common confluence is in a tract of country which has no more than 6 inches rain in the year. The great floods which they all bring down in the rainy season are of course chiefly due to the more copious rainfall in the hill country from which they come. To meet in some measure the local want of water thus increasing southward, the rivers are made to give off part of their supplies in canals, which fill as the river rises. Canals, carrying water permanently throughout the year, are drawn off from some of the rivers in the upper part of their course near the foot of the hills, and are carried along high land for the supply, all the way, of the country right and left. So great areas of land are protected against the possible effects of their scanty and precarious rainfall. Where these canals and their branches flow, the level of water in the wells is raised, and thus more advantage can be taken of the great sheets of water at varying depths below the surface. In the country through which run the dry channels of the Saraswati, Gaggar, Markanda, &c., the depth of the wells is very great, but the rainfall, though small (about 18 inches), is much greater than in the country to the west, at the tail of the Punjab rivers.

Besides the windings and changes of channels for short distances, with general maintenance of the same line, there are deviations on a larger scale, rivers forsaking old lines and taking an entirely new course. One well-known instance of this among the Punjab rivers is that of the Rávi, of which a deserted channel is traceable for a long distance in the Lahore and Montgomery districts.

The Punjab rivers are of different colours, depending on the soil through which they have passed and the tributaries they have received. The different colours of two rivers is often observable for a long distance below their confluence. The Indus below Attak is dull blue; its tributaries in this part of its course are red, except the Harro, which is light in colour and comparatively clear. The Ghana (Satlaj) is light but not clear where it is joined by the red Chináb, and they run on for a long way not mixed.

The united rivers which join the Indus are of less volume and velocity than its single stream. The width of the Panjnad (the combined five) is more than twice that of the Indus, but its depth is smaller and the rate of its current less than one-half. In the low season the discharge of the Indus is 92,000 cubic feet per second, and of the Panjnad 69,000—in all 161,000. The flood discharge in the month of August below the junction has been estimated at 446,000 cubic feet.

Such rivers are great powers, very valuable, and difficult to deal with. By watching their characters, and obeying while controlling the action of nature, we can do much to make them subservient to our purposes, and in some measure to illustrate man's influence on the physical as well as political geography of a country.

TUESDAY, SEPTEMBER 15.

The following Papers were read:—

1. *Antarctic Research.*
By Admiral Sir ERASMUS OMMANNEY, *C.B., F.R.S., F.R.G.S.*

The object of this paper was to draw attention to the neglect of the Antarctic region as a field for exploration. The author gave a summary of the work which has already been done by Cook, Bellingshausen, Weddell, Biscoe, Balleny, Wilkes, Dumont d'Urville, James Ross, and Nares (in the *Challenger*), and referred to a paper by Dr. Neumayer on the subject, the substance of which was reproduced in 'Nature,' vol. vii. The author concluded as follows:—'I have thus laid before you but a very imperfect description of these voyages; to give the details of the scientific results would occupy a separate paper. But I have endeavoured to demonstrate how large a field remains open for discovery. I think, from all we now know, we may infer that the South Pole is capped by an eternal glacier; and, from the nature of the soundings obtained by Ross, it would appear that the great ice-wall along which the ships navigated was the termination of the glacier—the source from which the inexhaustible supply of icebergs and ice-islands are launched into the Southern Ocean, many of which drift to the low latitude of 42°. The fact of finding the volcanoes of equal proportions to Etna or Mont Blanc creates a zest for further research regarding that awful region on which neither man nor quadruped ever existed. No man has ever wintered in the Antarctic zone. The great desideratum now before us requires that an expedition should pass a winter there, in order to compare the conditions and phenomena with our Arctic knowledge. The observations and data to be collected there throughout one year could not fail to produce matter of the deepest importance to all branches of science. I believe that such an achievement can be accomplished in these days with ships properly designed and fitted with the means of steam propulsion; nor is it chimerical to conceive a sledge party travelling over the glacier of Victoria Land towards the South Pole, after the example of Nordenskjöld in Greenland.

'Another interesting matter requires investigation, from the fact that all the thermometers supplied for deep-sea temperatures to Ross were faulty in construction, as they were then not adapted to register accurately beneath the weighty oceanic pressure. Moreover, another magnetic survey is most desirable, in order to determine what secular change has been made in the elements of terrestrial magnetism after an interval of forty years and more, when taken by Ross. In fact, there exists a wide field open for investigation in the unknown South Polar Sea. This paper will, I trust, be the prelude for others to follow in arousing geographers and this powerful Association in promoting further research by despatching another South Polar expedition, having for its object to secure a wintering station. No other nation is so capable of providing and carrying it out. Even in the Australian colonies there exists the spirit and the means for such a noble enterprise.' And he also directs the public attention to the fact that the only scientific information yet procured in the South Polar region within the Antarctic circle is limited to the observations collected by the *only* expedition ever despatched from this nation expressly for scientific research.

---

2. *Geographical Education.* *By* J. Scott Keltie.

The author mainly confined himself to the chief points in the Report on Geographical Exploration which he recently presented to the Royal Geographical Society. In this country, he stated, the position of geographical education is in a hopeful condition in elementary schools. The programme prescribed by the Education Department is satisfactory, and teachers seem to be practically getting into the way of carrying it out efficiently.

In the chaotic mass of middle class schools the position is far from satisfactory. The previous efforts of the Society and of the Oxford and Cambridge local examinations have had a beneficial influence, and numerous teachers here and there are found who recognise the educational value of geography, and do their best to teach it adequately. But as a rule it scarcely counts at all as a subject of education. This partly arises from the overcrowded state of school programmes, and partly because teachers themselves are ignorant of the subject and have no taste for it. The higher we ascend in the various grades of schools, the less do we find geography attended to. It appeared to the author that the wretched place which geography holds in our schools, and the barren results which in too many cases follow its teaching, is largely due to the narrow conception which prevails of what is known as political geography. Until we got beyond this fruitless conception of the subject, until we came to realise that political geography is really the resultant of ever so many factors, of the interaction not only between man and man, but between man and his physical surroundings, and until teachers are trained to bring the subject in this aspect before their pupils, it will never be other than the dull barren task it now is. (The paper is published in full in the 'Scottish Geographical Magazine,' October 1885.)

---

3. *On Overland Expeditions to the Arctic Coast of America.* *By* John Rae, *M.D., LL.D., F.R.S., F.R.G.S.*

Hearne, 1771.

There are records as early as 1715 that information was brought to the Hudson's Bay Company's fort at Churchill, Hudson's Bay, by the Indians, of there being a great river falling into the Arctic Sea many days journey to the northwest, the banks of which abounded in minerals, and the Indians frequently brought pieces of pure copper said to have been found there.[1]

It was to see these copper-mines, and also to get to the Arctic Sea, that Hearne made a very long journey with Indians, who treated him with great indignity and contempt, and he met with much suffering and privation, besides witnessing a horrible massacre of poor Eskimos by his savage companions, being unable to save even one poor young girl, that was stabbed to death whilst clinging to his knees for protection. Hearne certainly reached the Arctic Sea, but his survey was so inaccurate that he placed the mouth of the Coppermine River 228 geographical miles too far north and 110 geographical miles too far west, so that his map was *worse* than useless.

McKenzie (afterwards Sir Alexander), 1789.

The Arctic Sea was next 'tapped' by McKenzie in 1789. He descended the magnificent river that so worthily bears his name in a bark canoe, the crew feeding themselves chiefly by fishing and shooting. He arrived at an island in latitude 69° N., near the shore of which he saw many white whales (*Beluga*) with indications of a rise and fall of tide, and came to the conclusion that he had reached the mouth of the river, in which belief he was found to be correct. In fact, all his positions were found to be as satisfactory as those of Hearne were the reverse.

[1] To this day all weapons and tools of the Eskimos near the Coppermine are made of copper.

Franklin, Richardson, Back, and Hood, 1821.

Thirty years elapsed before the Arctic coast was again visited by an overland Arctic expedition, one of the most disastrous and pitiable ever known, although commanded by one of the best and bravest of men, assisted admirably by Dr. Richardson, a man gifted with all kinds of scientific knowledge and numerous other sterling qualities, that so peculiarly fitted him for the position of medical man and naturalist to the expedition.

Leaving England in 1819, two summers' travelling by boats and canoes through the Hudson's Bay Company's territory took the party in 1820 to winter quarters, named Fort Enterprise, some distance north of Great Slave Lake. On opening of the navigation in spring 1821 two canoes descended the Coppermine River and turned eastward, the object being to trace the coast as far as possible in that direction with the hope of meeting Parry, who about that date was exploring with two ships on the east coast of Melville peninsula, in hopes of finding a passage westward.

For five weeks the expedition struggled gallantly on, hampered by ice, stopped by storms, and on 'short commons' for food, but making only 150 miles easting. Parry at the time was more than 600 miles farther east. The canoes were abandoned in Hood River, and two small ones (a *mistake*) made out of them for crossing streams, &c. On the last day of August they began the overland journey towards Fort Enterprise, which in a straight line was 170 miles distant. The sufferings and privations from cold and hunger were simply terrible; much of their food was a very unpalatable lichen (*tripe de roche*), with short allowance of roasted bones and skin. The men's loads were so heavy [*foolishly so*—J. R.] that when they did kill large game little or none of the meat could be carried on.

Ten of the party perished miserably, two of these being shot—the one murdered, the other the murderer.

All the officers except poor Mr. Hood got back to England safe and well, after having been treated by the Indians—who brought them food when at death's door —'with a kindness and humanity that would have done honour to the most civilised of peoples.'

Franklin and Richardson, Back, and Kendall, 1826.

This expedition was as successful as the former one (1821) was unfortunate. Winter quarters were at Fort Franklin, Great Bear Lake. Four boats descended the McKenzie in spring 1826, and separated near the mouth of the river, becoming actually two expeditions, Franklin and Back in two boats going to the west, whilst Richardson and Kendall took the opposite direction, their destination being the Coppermine River, which they reached without difficulty, left their boats and walked overland to Bear Lake, where there was a boat waiting, in which they took passage to Fort Franklin. The western party were not so fortunate, having been compelled to turn back when 160 miles short of Point Barrow, to which place the barge of H.M.S. 'Blossom' (Captain Beechey) had come from the west the same season. The expedition got back to England in 1827.

Back, 1833-34.

In 1832 much anxiety began to be felt for Sir J. Ross's expedition to the Arctic in the little vessel 'Victory,' which left England in 1829, and a party under Captain Back was sent overland to search for them by way of the Great Fish River. Whilst wintering at the east end of Great Slave Lake in 1833-34 news was received that Sir J. Ross had got home; nevertheless, Back went down the river named after him, and explored more than 100 miles of the coast near its mouth, then returned to Fort Reliance, where another winter was spent, and returned to England the following summer (1835).

Hudson's Bay Company's Expedition, under Dease and Simpson, 1837, 1838, and 1839.

Several parts of the coast still remained untraced, and two of these gaps were completed in a very satisfactory manner by the above expeditions. In the first

year (1837) the 160 miles to the west—which Franklin could not reach—were traced. In the two following years, partly on foot, but chiefly in boats down the Coppermine, they went east, even *beyond* Back's survey of the mouth of the Fish River, thus accomplishing a boat voyage of more than 1,400 geographical miles, the longest ever made in boats on the Arctic coast, on which they remained until September 16, a dangerously late period. Dease and Simpson's tracing of new ground amounted to 667 geographical miles, but to do this 800 miles of previous survey had to be gone over. Simpson was awarded the Royal Geographical Society's Gold Medal when less than half his Arctic work was accomplished.

Rae, 1846–47, 1850–51, and 1853–54.

The first and last of these expeditions were equipped in 1846 and 1853 at York Factory, and wintered at Repulse Bay on the Arctic circle; the first in a stone house, the last in a snow-hut, which proved by far the more comfortable of the two, although they had no fire to give warmth in the one, nor a 'fire-lamp,' such as the Eskimos use, in the other. In the stone house the temperature fell 15° or 20° during the cooking of our two meals—frequently only one—per day, as the door had to be kept open to allow the smoke to escape which would not go up the chimney. The first party consisted of Rae, ten men and two Eskimos; the last of eight persons. On each occasion venison and fish sufficient for eleven or twelve months were obtained, nearly half the deer for winter use being shot by Rae. In 1847 the first long sledge journeys ever made on the Arctic shores of America were performed, more than 1,200 miles in distance, uniting Ross's discoveries on Boothia with those of Parry on Melville peninsula, all but a few miles.[1] The cost of this expedition was less than 1,400*l.*

In 1854 a sledge journey of about 1,100 miles, at the rate of nearly 20 miles a day, was made, uniting the surveys of Dease and Simpson to those of Ross, west of Boothia, and proving King William's Land to be an island. The work done by these two expeditions was the tracing 933 miles of new land, the obtaining of the first information (in 1854) of the fate of the Franklin Expedition, and the making four voyages of 900 miles each in open boats along a dangerous coast, all at a cost of less than 3,000*l.* for both.

In 1850 Rae, whilst in charge of McKenzie River District, was asked by the Admiralty to go in search of the missing expedition, and to take any route he thought best. There was only one route open, that by Great Bear Lake and the Coppermine River, which could not be utilised until 1851, as small boats had to be built suitable for hauling overland. It was confidently stated that no wood fit for boatbuilding could be obtained on the east side of Great Bear Lake, yet this difficulty was overcome, and Indians as hunters were searched for and found. Two nice little boats were built by the carpenter, who, although a good workman, did not know the form of boat required, so Rae's experience of many years before in the Orkney Islands became useful, as he not only drafted the boats to scale in every plank, but cut out and roped the sails, and fitted and spliced the rigging and other gear.

A sledge journey of more than 1,000 miles was made by Rae, two men, and three half-starved dogs, to the coast and along Wollaston Land, at the rate of 24 miles a day, all the party hauling or carrying loads the whole way. The boat voyage to the eastward of the Coppermine was 1,350 miles, partly along the coast of Victoria Land, and up Victoria Strait to a higher latitude than that where Franklin's ships were abandoned in 1848, near King William's Island, on the east side of the strait, which was filled with immense heaps of rough ice in 1851. On returning to the Great Bear Lake an effort was made to get south before the closing of the river navigation, but the boat was frozen up in Athabasca River. From this place the party travelled on snowshoes 1,300 miles (at the rate of 27 miles a day) to Red River[2] where all the men were paid off except two, who accompanied Rae to the United States 450 miles in ten days, being aided by dogs.

[1] A slight error in the chart, which was relied upon as correct, gave to Parry's Survey a few more miles than was correct.

[2] Gold medal of R. G. S. awarded in 1852.

As the searching expeditions of Richardson and Rae, in 1848, of Rae, 1849, of Pullen, 1849–50, and of Anderson and Stewart, 1855, obtained no new geographical results, no details are given of these.

APPROXIMATE AMOUNT OF GEOGRAPHICAL WORK DONE BY THE EXPEDITIONS NORTH OF ARCTIC CIRCLE UNDER—

			G. M.		G. M.	G. M.
1821.	Franklin & Richardson	on foot	35	in canoes	415	450
[1] 1826.	" "	"	90	in boats	955	1,045

1847. [3] 1851. 1853–4.	Rae (H. B. Co.)	sledging on foot	1,123	in boats	369	1,492
				Grand total		4,029

4. *On the best and safest Route by which to attain a High Northern Latitude.* *By* JOHN RAE, *M.D., LL.D., F.R.S., F.R.G.S.*

The plan proposed is that the route by the west shore of Spitzbergen should be taken by one, or perhaps two, steamers similar to the fine vessels used in sealing and whaling at the present time. That after forcing the ice 'pack' at the north-west end of Spitzbergen, a north-east course towards Francis Joseph Land should be followed. That a depôt of coals should be placed at a convenient harbour in North Spitzbergen. Extracts are given from Parry's 'Narrative,' 1827, pp. 101 and 148, showing how open and small the ice was in latitude 82° 45′ N. The southern drift of the ice that so obstructed the advance of Parry's boats will be no great impediment to a powerful steamer, whilst if she gets helplessly fixed in the pack she will drift homewards with it. No well-equipped and powerful steamer has tried this route.[4]

5. *Oceanic Islands and Shoals.* *By* J. Y. BUCHANAN.

6. *On the Depth of the permanently Frozen Stratum of Soil in British North America.* *By* General Sir J. HENRY LEFROY, *K.C.M.G., F.R.S.*

7. *On Recent Explorations in New Guinea.* *By* COUTTS TROTTER.

The author desired to bring our knowledge of the country up to date by some notes on what has been done there since 1883, when he read a paper on New Guinea before the Association. He calls attention to the results of Mr. Chalmers's journeys in the south-eastern peninsula, which have added considerably to our knowledge of the physical features of the region. Proofs have been found near Yule island of intercourse with the inhabitants of the northern coast, and this, coupled with native reports, leads to the belief that a route across the country will

[1] Actually two expeditions, one east, the other west.

[2] Dease and Simpson had to pass over about 800 miles of previously traced coast before getting to new ground, but Franklin and Richardson were on new ground at once on reaching the coast.

[3] Of the coast, &c., traced by Rae, 1,123 miles were done by sledging, believed to be the most laborious of Arctic work.

[4] Parry found the ice floes so small in latitude 82° 45′ N, that only one piece could be found large enough and strong enough to haul his boats upon.

be found in that direction. The numerous so-called 'temples' found near the head of the Gulf of Papua, with a priestly class attached to them, is remarkable, and argues a decided mixture of race, pointing in fact to the prevalence of Polynesian as opposed to Papuan religious ideas.

After referring to the hydrographical problems suggested by the character of the country on the Gulf, and further west, at Onin, Mr. Trotter discusses the probable importance of the recent ascent of the Amberno river, an account of which, translated from the Dutch, was contributed by him to the Royal Geographical Society's Proceedings for March last. He adds some notice of surveys by the Germans of the territory recently annexed by them, parts of which opposite to the island of New Britain appear to offer a fairer prospect to settlers than any other district as yet discovered in New Guinea.

The author takes an unfavourable view of the effect on the interests of the natives of the conflicting jurisdictions, and differing ways of treatment, to which they will now be subjected. This paper will be found *in extenso* in the 'Scottish Geographical Magazine' for October, 1885.

WEDNESDAY, SEPTEMBER 16.

The following Papers were read:—

1. *On Journeyings in South-Western China. By* A. HOSIE.

In the autumn of 1881 Mr. Hosie was appointed Her Majesty's Agent in Western China, and reached Ch'ung-ch'ing, in the province of Ssŭ-ch'uan, in January 1882. From this point he made three journeys in South-Western China. In the spring of 1882 he proceeded through Southern Ssŭ-ch'uan and Northern Kuei-chou, the Chinese 'Switzerland,' to Kuei-yang Fu, the capital of the latter province, whence he journeyed westward in the footsteps of Margary to the capital of Yünnan. From Yünnan Fu he struck north-east through Northern Yünnan, following for days here and there the routes of Garnier and the Grosvenor Mission. At last he descended the Nan-kuang River and reached the right bank of the Great River, the local name of the Upper Yangtsze, at a point below Hsü-chou Fu, an important city at the junction of the Min River and the Chin-sha Chiang, or River of Golden Sand. Here he took boat and descended the Great River to Ch'ung-ch'ing, his starting-point.

In February 1883 Mr. Hosie again left Ch'ung-ch'ing, and proceeded north-west to Ch'êng-tu, the capital of the province of Ssŭ-ch'uan, by way of the brine and petroleum wells of Tzŭ-liu-ching. From Ch'êng-tu he journeyed west and south-west through the country of the Lolos, skirting the western boundary of Independent Lolodom. From Ning-yüan, locally called Chien-ch'ang, and lying in a valley famous, among other things, as the habitat of the white-wax insect, he passed south-west through the mountainous Cain-du of Marco Polo, inhabited in great part by Mantzŭ tribes, and struck the left bank of the Chin-sha Chiang two months after leaving Ch'ung-ch'ing. From this point Ta-li Fu, in Western Yünnan, was easily reached. From Ta-li Fu Mr. Hosie journeyed eastward to Yünnan Fu, which he had visited the year before, and then struck north-east through Western Kuei-chou to the Yung-ning River, which he descended to the Great River. Lu Chou, an important city at the junction of this river with the T'o River, was soon reached, and the Great River was again descended to Ch'ung-ch'ing. This journey occupied four months.

In June 1884 Mr. Hosie again left Ch'ung-ch'ing, and from Ho Chou, a three days' journey to the north of that city, he struck westward through a beautifully cultivated and fertile country to Chia-ting Fu, on the right bank of the Min at its junction with the T'ung River. Chia-ting is famous as the great centre of sericulture in Ssŭ-ch'uan, and as the chief insect wax producing country in the Empire.

A day's journey west of Chia-ting is the famous Mount O-mei, rising 11,100 feet above the level of the sea. This mountain, which is sacred to the worship of Buddha, Mr. Hosie ascended in company with crowds of pilgrims. He then proceeded south, skirting the eastern boundary of Independent Lolodom, to the River of Golden Sand, the left bank of which was struck at the town of Man-i-ssŭ, between forty and fifty miles above P'ing-shan Hsien—the highest point reached by the Upper Yangtsze Expedition in 1861. From Man-i-ssŭ Mr. Hosie descended the Chin-sha Chiang and the Great River to Ch'ung-ch'ing.

5. *What has been done for the Geography of Scotland, and what remains to be done.*[1] *By* H. A. WEBSTER.

After explaining that he wished rather to offer a few practical suggestions for the future than to be the mere chronicler of the past, he gave a brief sketch of the various contributions made to the map of Scotland previous to the establishment of the Ordnance Survey, calling attention more especially to the wonderful peregrinations of Timothy Pont, a reproduction of whose maps and notes in their entirety would be worth the attention of some of our publishing societies. He next proceeded to point out that, admirable as the labours of the Ordnance Survey admittedly were (and, for one thing, they for the first time enabled the geographer to form a true idea of the vertical development of the country), they could not be considered complete until certain *lacunæ*, especially as regards altitudes, were filled up, and until the general results were rendered more readily available by being co-ordinated in an official handbook. The parochial character of the details registered in the area-books of the survey rendered them practically useless to the geographer. Even were he content to accept the parish as the unit of description (and a more absurd one could hardly be found), it was only by a tedious arithmetical process he could discover how much of this area was occupied by land and how much by water, how much was arable and how much forest. To all such questions as, What is the length of this river? What is the extent of its basin? To what distance is it navigable? To what distance does the tide ascend? How much of this or that area lies between 500 and 1,000 feet? how much between 1,000 and 1,500 feet? and so on, the maps of the Survey might be said to contain the answers, but in most cases they contained them, so to speak, only in solution. No *accurate* measurement, for example, appeared to have been made of the river-basin areas; and, according to Mr. Stanford's estimate, it would cost a private person 20*l.* to get the necessary operations performed. Even the accurate measurement of all the development lengths of the rivers would be a tedious task. But to several of the questions which the geographer naturally asks the Ordnance Survey maps supplied no answer in any form. We had the altitude of many of the lakes, but for some of the more important ones no precise figures were given. In some cases the area-books of the parishes enabled us to find the areas of the lakes; in other cases they did not. In regard to the depth of our lakes and rivers—and the submerged portion of a valley is geographically as interesting as the sub-aërial portion—absolutely no

[1] Printed *in extenso* in *The Scottish Geographical Magazine*, October 1885.

data were supplied by the Ordance Survey. Nor, with a few individual exceptions, did they exist in an accurate and trustworthy form anywhere else. It was an open secret that, when this omission was pointed out to the Government by the Royal Societies of London and Edinburgh, the Lords of the Treasury refused, and again refused, to authorise a bathymetric lake and river survey being carried out, either by the officers of the Ordnance Survey or by those of the Hydrographic department. Such a refusal could not be permanently accepted. It was to be hoped that when the Government was next urged to move in the matter they would be asked for more, and not for less. We required not only a hydrographic survey done once and for all (though that was worth the doing); we required a systematic registration of hydrographic facts throughout the country, in order that the true *régime* both of lakes and rivers might be known in detail and with scientific precision. The ignorant niggardliness of the British Government was in striking contrast to the conduct of those of some foreign countries. In Switzerland, for instance, there was a regular system of inland hydrographic observations, by which the *régime* of all the principal rivers was annually recorded and rendered easily intelligible by a series of graphic bulletins. In regard to a Swiss river, we could tell the volume at any period of the year at several important points, and could compare the facts of 1884, for instance, with those of any year in the last two decades. Everyone knew what a vast body of interesting data had for generations been accumulating about such rivers as the Po and the Rhone, and many had no doubt heard of the system of hydrographic stations recently established by the Italian Government in the basin of the Tiber. Why should we not endeavour to learn something definite and precise about the character of our own rivers? The investigation was only the natural complement on the one hand of the physical structure of the country, and on the other hand of its meteorology. Our Scottish Meteorological Society had now succeeded in establishing meteorological stations throughout the country; let hydrographic stations bear them company along our principal rivers. Rainfall and river discharge were mutually illustrative. Another matter, not so directly of geographic import, might be mentioned in passing—the investigation of the different chemical qualities of the waters of the different lakes and rivers. But, to proceed to a strictly geographical matter, it had been frequently pointed out that unfortunately the results of the coast surveys had not been incorporated in the seaward portions of the Ordnance Survey maps; nor, indeed, was the submarine portion of our island group sufficiently attended to in any of our physical maps. A special interest attached to the hollow of the North Sea, but a good deal remained to be done before the demands of modern research would be satisfied. Good work was happily beginning to be carried on at Granton and elsewhere in regard to the difference of salinity, &c., between the water of this almost land-locked basin and that of the open Atlantic.

Turning from the physical to the political or administrative geography of Scotland, the reader briefly called attention to the fact that while we had elaborate studies of the Ptolemaic geography of the country, and attempts such as those of Cosmo Innes, to reconstruct the civil and ecclesiastical divisions of certain periods, the detailed history of the rise of the Scottish counties, and of the fixing of the Scottish-English border would furnish subjects for difficult but interesting investigation. He then referred at some length to the desirableness and possibility of collecting and elucidating the whole *corpus* of Scottish place-names. Important studies in this department had been already made by Dr. Skene, Captain Thomas, and others; but what was now wanted was a complete system of registration, and a co-operative system of historical and philological illustration. Of such a treatment of national place-names the Netherlands afforded a most instructive example. The Publications Committee of the Scottish Geographical Society was endeavouring to organise a special committee in connection with the subject. In conclusion, though it might be said that the subject was rather sociological than geographical, attention was called to the necessity of a greater application of cartography to the rendering of statistical facts, such as those of density of population, birth and death rates, distribution of trade and commerce, education, &c. Augustus Petermann, at the census of 1851, set an admirable example to our census authorities,

but they failed to follow it. One could actually get a clearer idea of the relative density of the population throughout the different parts of the United Kingdom from Petermann's map than from anything that had since been published. In this matter of applied cartography, Scotland (and it might be added England also) was deplorably behind most foreign countries—notably Germany, France, and Italy. To some extent this might be the fault of the cartographers, but to a larger extent it was due to the small attention that was bestowed on the *systematic* collection of statistical information in such a form as can be tabulated or 'graphicised.' Nothing was more difficult in many cases than to obtain statistical facts for any smaller totality than the United Kingdom. It was time that an attempt should be made to compile, under the auspices of some authoritative institution, such as the Royal Society of Edinburgh, a new statistical account of Scotland: though such a work as Mr. Groome's 'Ordnance Survey Gazetteer' did much to supply the desideratum, the enterprise was too difficult for private accomplishment.

---

6. *On Bathy-hypsographical Maps, with special reference to a Combination of the Ordnance and Admiralty Surveys. By* E. G. Ravenstein, *F.R.G.S.*

The bathy-hypsographical map, which exhibits the vertical configuration of the solid surface of the earth above as well as below the ocean-level, is a product of modern times. It was Gerard Mercator who first inserted soundings upon a chart in 1585, but nearly two centuries passed away before Cruquius, in 1728, introduced the fathom-lines with which we are all familiar. Buache, and after him Ducarla, first suggested the introduction of contours upon maps, and their idea was realised in 1791 by Dupain-Triel on a map of France. The combination of these two descriptions of contoured maps we owe to modern German geographers, and more especially to Berghaus, von Sydow, and Ziegler. Cartographers in effecting this combination had hitherto quite lost sight of the fact that the heights on maps are referred to high or mean water, whilst the depths on charts represent soundings reduced to low water. This rough method gave satisfactory results when dealing with maps on a small scale, but a more rigid method would have to be applied when it was desired to combine accurate surveys like those made by the Ordnance and Admiralty departments. The so-called mean level of the sea was not a suitable datum level, and it would be necessary to carry on tidal and other scientific observations on a far more comprehensive plan than had been done hitherto if a really satisfactory bathy-hypsographical map of the British islands were to become attainable. These various supplementary surveys, tidal observations, &c., it was to be hoped, would expand into a comprehensive scientific survey of the British seas.

SECTION F.—ECONOMIC SCIENCE AND STATISTICS.

PRESIDENT OF THE SECTION—Professor HENRY SIDGWICK, M.A., Litt.D.

THURSDAY, SEPTEMBER 10.

The following Report and Papers were read:—

1. *Report of the Committee for continuing the inquiries relating to the Teaching of Science in Elementary Schools.*—See Reports, p. 692.

The PRESIDENT delivered the following Address:—

I HAVE chosen for the subject of the discourse, which by custom has to be delivered from the chair that I am called upon to occupy, the scope and method of economic science, and its relation to other departments of what is vaguely called 'social science.' If the abstract and academic nature of the subject, together with my own deficiencies as an expositor, should render my remarks less interesting to the audience than they have a right to expect, I trust that they will give me what indulgence they can; but, above all, that they will not anticipate a corresponding remoteness from concrete fact in the discussions that are to follow. I see from the records of the Association that it has been the custom in this department—and it seems to me a good custom—to give to the annual addresses of the presidents the variety that naturally results when each speaker in turn applies himself unreservedly to that aspect of our complex and many-sided inquiry which his special studies and opportunities have best qualified him to treat; and as my own connection with economic science has been in the way of studying, criticising, and developing theories, rather than collecting and systematising facts, I have thought that I should at any rate have a greater chance of making a useful contribution to our discussions if I allowed myself to deal with the subject from the point of view that is most familiar to me.

I have the less scruple in adopting this course because I do not think that any who may listen to my remarks are likely to charge me with overrating the value of abstract reasoning on economic subjects, or regarding it as a substitute for an accurate and thorough investigation of facts instead of an indispensable instrument of such investigation. There is indeed a kind of political economy which flourishes in proud independence of facts, and undertakes to settle all practical problems of Governmental interference or private philanthropy by simple deduction from one or two general assumptions—of which the chief is the assumption of the universally beneficent and harmonious operation of self-interest well let alone. This kind of political economy is sometimes called 'orthodox,' though it has the characteristic unusual in orthodox doctrines of being repudiated by the majority of accredited teachers of the subject. But whether orthodox or not, I must be allowed to disclaim all connection with it; the more completely this survival of the *à priori* politics of the eighteenth century can be banished to the remotest available planet, the better it will be, in my opinion, for the progress of economic

science. Since, however, this kind of political economy is still somewhat current in the market-place, since the language of newspapers and public speakers still keeps up the impression that the professor of political economy is continually laying down laws which practical people are continually violating, it seems worth while to try to make clear the relation between the economic science which we are concerned to study and the principles of Governmental interference—or rather non-interference—which are thought to have been of late so persistently and in some cases so successfully outraged.

It must be admitted at once that there is considerable excuse for the popular misapprehension just mentioned; since for more than a century the general interest taken in the analysis of the phenomena of industry has been mainly due to the connection of this analysis with a political movement towards greater industrial freedom. No researches into the historical development of economic studies before Adam Smith can displace the great Scotchman from his position as the founder of modern political economy considered as an independent science, with a well-marked field of investigation and a definite and peculiar method of reasoning. And no doubt the element of Adam Smith's treatise which makes the most impression on the ordinary reader is his forcible advocacy of the 'system of natural liberty;' his exposition of the natural 'division of labour'—tending, if left alone, to become an international division of employments—as the main cause of the 'universal opulence' of 'well-governed' societies; and of the manner in which, in this distribution of employments, individual capitalists seeking their own advantage are led 'by an invisible hand' to 'prefer that employment of their capital which is most advantageous to society.'

At the same time Adam Smith was too cool and too shrewd an observer of facts to be carried, even by the force and persuasiveness of his own arguments, into a sweeping and unqualified assertion of the universality of the tendency that he describes. His advocacy of natural liberty in no way blinds him to the perpetual and complex opposition and conflict of economic interests involved in the unfettered efforts of individuals to get rich. He even goes the length of saying that 'the interest of the dealers in any particular branch of trade or manufacture is always in some respects different from, and even opposite to, that of the public.' To take a particular case, he is decidedly of opinion that the natural liberty of bankers to issue notes may reasonably be restrained by the laws of the freest Governments. He is quite aware, again, that the absence of Governmental interference does not necessarily imply a state of free competition, since the self-interest of individuals may lead them, on the contrary, to restrict competition by 'voluntary associations and agreements.' He does not doubt that Governments, central or local, may find various ways of employing wealth—of which elementary education is one of the most important—which will be even economically advantageous to society, though they could not be remuneratively undertaken by individual capitalists. In short, however fascinating the picture that Adam Smith presents to us of the continual and complex play of individual interests constituting and regulating the vast fabric of social industry, the summary conclusion drawn by some of his disciples that the social production of wealth will always be best promoted by leaving it altogether alone, that the only petition which industry should make to Government is the petition of Diogenes to Alexander that he would cease to stand between him and the sunshine, and that statesmen are therefore relieved of the necessity of examining carefully the grounds for industrial intervention in any particular case—this comfortable and labour-saving conclusion finds no support in a fair survey of Adam Smith's reasonings, though it has been no doubt encouraged by some of his phrases. To attribute to him a dogmatic theory of the natural right of the individual to absolute industrial independence—as some recent German writers are disposed to do[1]—is to construct the history of economic doctrines from one's inner consciousness.

It is true, as I have said, that among Adam Smith's disciples there were not a

[1] *E.g.*, v. Scheel, in Schönberg's *Handbuch der politischen Oekonomie*, p. 89, speaks of 'Die naturrechtliche Wirthschaftstheorie oder der Smithianismus.'

few who rushed to the sweeping generalisations that the master had avoided. In England, in particular, the influence of the more abstract and purely deductive method of Ricardo tended in this direction. It was natural, again, that in the heat of a political movement absolute and unqualified statements of principle should come into vogue, since the ease and simplicity with which they can be enunciated and apprehended makes them more effective instruments of popular agitation: hence it is not surprising to find the Anti-Corn-law petitions declaring the 'inalienable right of every man freely to exchange the result of his labour for the productions of other people,' to be 'one of the principles of eternal justice.' But under the more philosophic guidance of J. S. Mill, English political economy shook off all connexion with these antiquated metaphysics, and during the last generation has been generally united with a view of political principles more balanced, qualified, and empirical, and therefore more in harmony with the general tendencies of modern scientific thought.

If, indeed, *laisser-faire* were—as many suppose—the one main doctrine of modern political economy, there can be no doubt that the decisive step forward that founded the science ought to be attributed not to Adam Smith, but to his French la predecessors the 'Physiocrats.' It is to them—to Quesnay, De Gournay, De Rivière, Turgot—that the credit, whatever it may be, is due of having first proclaimed to the world with the utmost generality and without qualification that what a statesman had to do was not to make laws for industry, but merely to ascertain and protect from encroachment the simple, eternal, and immutable laws of nature, under which the production of wealth would regulate itself in the best possible way if men would abstain from meddling.

This doctrine formed one part of the impetuous movement of thought against the existing political order which characterised French speculation during the forty years that preceded the great Revolution. It was, we may say, the counterpart and complement of the doctrine of which Rousseau was the chief prophet. The sect of the Économistes and the disciples of Rousseau were agreed that the existing political system needed radical change; and in both there was a tendency to believe that an ideal political order could at once be constituted. At this point, however, their courses diverged: the school of Rousseau held that the essential thing was to alter the *structure* of government, and to keep legislation effectually in the hands of the sovereign people; the Économistes thought that the all-important point was to limit the *functions* of government, holding that the simple duty of maintaining the natural rights of the individual to liberty and property could be best performed by an absolute monarch. Both movements had much justification; both have had effects on the political and social life of Europe of which it is difficult to measure the extent; but both doctrines—attained, as they were, by a fallacious method—involved a large element of exaggeration, suitable to the ardent and sanguine period that brought them forth, but which gives them a curious air of absurdity when they are resuscitated and offered for the acceptance of our more sober, circumspect, and empirically-minded age. In the most civilised countries of Europe it is now a recognised and established safeguard against oppressive laws that an effective control over legislation is vested in the people at large: but no serious thinker would now maintain with Rousseau that the predominance of the will of the sovereign people has a necessary tendency to produce just legislation. Similarly, the doctrine of the Physiocrats has prevailed, in the main, as regards the internal conditions of national industry in modern civilised societies. The old hampering privileges, restraints, and prohibitions have been almost entirely swept away, to the great advantage of the community; but the absolute right of the individual to unlimited industrial freedom is now only maintained by a scanty and dwindling handful of doctrinaires, whom the progress of economic science has left stranded on the crude generalisations of an earlier period.

There will probably always be considerable disagreement in details among competent persons as to the propriety of Governmental interference in particular cases; but, apart from questions on which economic considerations must yield to political, moral, or social reasons of greater importance, it is an anachronism not

to recognise fully and frankly the existence of cases in which the industrial intervention of Government is desirable, even with a view to the most economical production of wealth. Hence, I conceive, the present business of economic theory in this department is to give a systematic and carefully-reasoned exposition of these cases, which, until the constitution of human nature and society are fundamentally altered, must always be regarded as exceptions to a general rule of non-interference. The statesman's decision on any particular case it does not belong to abstract theory to give; this can only be rationally arrived at after a careful examination of the special conditions of each practical problem at the particular time and place at which it presents itself. But abstract reasoning may supply a systematic view of the general occasions for Governmental interference, the different possible modes of such interference, and the general reasons for and against each of them, which may aid practical men both in finding and in estimating the decisive considerations in particular cases. Thus it may show, on the one hand, under what circumstances the inevitable drawbacks of Governmental management are likely to be least, and by what methods they may be minimised; and where, on the other hand, private enterprise is likely to fail in supplying a social need—as where an undertaking socially useful is likely for various reasons to be unremunerative to the undertakers—or where private interests are liable to be markedly opposed to those of the public, as is generally the case with businesses that tend to become monopolies.

It would be tedious now to dwell at length on these generalities; but there is one special exception to the triumph of the system of natural liberty in the civilised countries of Europe which has too much historical importance to be passed over without a word in this connection. As we are all aware, this triumph has only been decided as regards the *internal* conditions of industry and trade; the practice of imposing barriers on *international* exchange, with a view to the protection of native industry, still flourishes in the most advanced communities, and shows no immediate tendency to come to an end. It is not, I conceive, reasonable to attribute this result entirely, as some Free-traders are disposed to do, to the incapacity of mankind to understand elementary economic truths, and the interested efforts of a combination of producers to prey in a comfortable and legal way on the resources of the confiding consumers. I do not deny that both these causes have operated; but, in view of the evident ability and disinterestedness of many of the writers and statesmen who have supported the cause of Protection on the Continent or in the United States, I cannot find in them an adequate explanation of the phenomenon.

A part of the required explanation is, I think, suggested when we examine the arguments by which Free-trade was actually recommended to intelligent Englishmen at the time when England's policy was taking the decisive turn in this direction, and imagine their effect on the mind of an intelligent foreigner. Suppose, for instance, that the intelligent foreigner is studying the *Edinburgh Review* in 1841, when it came forward as a vigorous and decided advocate of Free-trade. In the January number he would find the cosmopolitan and abstract argument with which we are so familiar; he would learn how, under Free-trade, 'every country will exert itself in the way that is most beneficial in the production of wealth;' how labour and capital will be employed in each country to produce those things which the varieties of climate, situation, and soil enable it to produce with greater advantage than other countries, so that 'the greatest possible amount of industry will be kept constantly in action, and all commodities will exist in the greatest abundance.' But in the July number of the same organ he would find a recommendation of Free-trade from a national point of view, which, though more restricted in its scope, would appear to contain matter no less important for practical consideration. He would find that the immediate introduction of Free-trade was held to be essential in order to keep what remained of the manufacturing and commercial supremacy of England. He would learn that 'the early progress of any nation that attempts to rival us in manufactures must be slow;' for 'it has to contend with our great capital, our traditionary skill, our almost infinite division of labour, our long-established perseverance, energy, and enterprise,

our knowledge of markets, and with the habits of those who have been bred up to be our customers.' He would learn that there was 'no reason to believe that,' in the 'absence of disturbing causes,' we should ever lose our present command of the world's market; that we might have preserved our superiority for centuries; but that 'if these difficulties were once surmounted, this superiority—so far at least as respects the commodity in which we find ourselves undersold—would be gone for ever,' in consequence of 'the well-known law of manufacturing industry that, *ceteris paribus*, with every increase of the quantity produced, the relative cost of production is diminished.' It cannot be denied that a consideration of this law, and of the *vis inertiæ* here attributed to an established superiority in manufactures and commerce, supplies an important qualification of the general argument for Free-trade. For, along with the tendency of industry to go where it can be most economically carried on, we have also to recognise a tendency for it to stay and develop where it has been once planted; and the advantage of leaving this latter tendency undisturbed would naturally be less clear to the patriotic foreigner than to the patriotic Englishman. The proclamation of a free race for all, just when England had a start which she might probably keep 'for centuries,' would not seem to him a manifest realisation of eternal justice; to delay the race for a generation or two, and meanwhile to apply judiciously 'disturbing causes' in the form of protective duties, would seem likely to secure a fairer start for other nations, and ultimately, therefore, a better organisation of the world's industry even from a cosmopolitan point of view.

Nor would it seem to him a conclusive argument against this course that protective duties impose great present pecuniary sacrifices on the protecting nation; especially when he learnt, from an impartial English source, of the great sacrifices which private capitalists in England were in the habit of making to assist the tendency of free competition in their favour. He would find, for instance, in the Report of a Commission published in 1854,[1] an appeal to the working classes to consider 'the immense losses which their employers voluntarily incur in bad times, in order to destroy foreign competition, and to gain and keep possession of foreign markets.' Should the efforts of Trade-Unionists, urges the writer, be successful for any length of time, they would interfere with the 'great accumulations of capital which enable a few of the most wealthy capitalists to overwhelm all foreign competition in times of great depression,' and which thus constitute 'the great instruments of warfare against the competing capital of foreign countries.' If it was the view of shrewd English men of business that these great sacrifices of private wealth were needed, and were worth making, to maintain the industrial start once gained, the intelligent foreigner would naturally conclude that the other combatants in the industrial battle must be prepared to make corresponding sacrifices; that each nation must fight with its own weapons; and that where there were no great accumulations of capital in private hands, the instruments of warfare must be obtained by a general contribution.

I have given these considerations, not because I agree with the practical conclusion which they tend to support, but because I think that they require to be met by a line of argument different from that which English economists have usually adopted. I think it erroneous to maintain, on the ordinary economic grounds, that temporary Protection must always be detrimental to the protecting country, even if it were carried out by a perfectly wise and strong Government, able to resist all influences of sinister and sectarian interests, and to act solely for the good of the nation. The decisive argument against it is rather the political consideration that no actual Government is competent for this difficult and delicate task; that Protection, as actually applied under the play of political forces, is sure to foster many weak industries that have no chance of living without artificial support, and to hamper industries that might thrive independently, by the artificial dearness of some of their materials and instruments; so that it turns out a dangerous and clumsy, as well as a costly, instrument of industrial competition, and is

[1] See p. 20 of Report by Mr. H. S. Tremenheere, Commissioner appointed to inquire into the operation of Act 5 & 6 Vict. c. 99, and into the state of the population in the mining districts (Vol. XIX. of Parl. Papers for 1854).

not likely on the whole to bring the desired victory, though it may give a partial success here and there. And some such conclusion as this is, I think, now prevalent even among those German economists who are most decided in their rejection of the claims of *laisser-faire* to absolute and unqualified validity.

So far I have been speaking of the function of economic science in determining principles of Governmental intervention in matters of industry, because this is the function prominent in the popular view of political economy. But I need hardly say to the present audience that this is not the view that English economists generally have taken as to their primary business. Indeed, during the last generation our leading economists—even those who come nearest to the so-called 'orthodox' type—have gone even further than I should myself go in declaring that economic science had nothing to do with the doctrine of *laisser-faire*. No one (*e.g.*) has stated this more strongly than Cairnes, whom I select as a conspicuous and effective advocate of Free-trade. 'The maxim of *laissez-faire*,' he says, 'has no scientific basis whatever;' it is a 'mere handy rule of practice,' though 'a rule in the main sound.' According to this view, the 'laws' with which economic science is primarily concerned are the laws that determine economic quantities—the amount of the aggregate of wealth, its annual increase, the relative values of its different elements, and the shares of the economic classes that have combined to produce it—as they would be apart from special Governmental interference; and not the rules for deciding when and how far such interference is justifiable.

And it is the additional light that Adam Smith threw on the general determination of such economic quantities—and not his advocacy of natural liberty—which in the view of economists constitutes his chief claim to his place in the historical development of economic science. And I may observe that, from this point of view, the important predecessors of Adam Smith are not the Physiocrats only, but even more Cantillon, who wrote a generation before, to whom Jevons drew attention some years ago in a remarkable essay; nor shall we overlook his English predecessors of a still earlier age, such as Petty and Locke—the former of whom has a special interest for us as a pioneer in each of the two lines of investigation of which we here maintain the union, since he was the first in England to combine a serious effort to establish the general relations of economic quantities by abstract reasoning and analysis with patient endeavours to ascertain particular economic facts by statistical inquiries. When we trace the gradual evolution of the modern economic view as to the manner in which the play of individual self-interests tends to determine prices and shares—from the rude beginnings of Petty and Locke, through the more systematic and penetrating theory of Cantillon, the fuller analysis and exposition of Adam Smith, and the closer reasoning of Ricardo, down to the important rectifications and additions of Jevons—we see clearly that the progress of the theory has no necessary connection with any doctrine as to the limits of the industrial intervention of Government.

And it is to be observed that neither Adam Smith nor the predecessors to whom I have referred had any design of maintaining that the distribution which they were endeavouring to analyse satisfied either the claims of ideal equity by giving each individual his deserts, or the claims of expediency by giving him what was most conducive to general happiness. Nor, since Adam Smith, has any leading English economist maintained the former of these propositions; and so far as the school of Ricardo may have seemed to maintain the latter—so far as they certainly have taught that direct Governmental interference with distribution was undesirable—it has not been from any prevalence among them of the shallow optimism of Bastiat and his followers. It is pessimism rather than optimism which is to be laid to their charge; not a disposition to underrate or ignore the hardships that the 'natural' rate of wages might entail; but a conviction that, however bad things might be naturally, the direct interference of Government could only make them worse. I am not arguing that they did not go too far in this view; I am now chiefly desirous to remove a profound and widespread misunderstanding as to the general aim and drift of their investigations, which I find in certain German and other Continental critics of English political economy, and, I may add, in certain English critics who repeat the foreign objections. Such critics either fail to

see, or continually forget, that the English economist, in giving an explanation of the manner in which prices, wages, profits, &c., are determined, is not attempting to justify the result; he is not trying to show that in getting the market price of his services the labourer, capitalist, or landlord gets what he deserves. Thus when Senior called interest the 'reward of abstinence,' he did not mean to imply that it was normally proportioned to the capitalist's merit in abstaining, but merely that capital is increased by individuals saving instead of spending, and that they require the inducement given by the actual rate of interest to save to the extent to which they actually are saving. Whether any other rate of interest would be *juster* is a question of ideal politics to which the English economist has usually nothing to say so long as it is stated in this abstract form; it is only when the political idealist descends to practice, and proposes a scheme for realising his conception of justice, that it comes within the province of economic science to discuss the probable effects of this scheme on production and distribution. But it is not with such far-reaching proposals of change that the English economist is mainly concerned; his primary business is to ascertain the causes which determine actual prices of products and services.

Hence, when the most recent German school of economists—variously known as the 'historical,' 'ethical,' or 'social' school—claims to have moralised political economy by throwing over the assumption of egoism, which they regard as characteristic of 'Smithianismus,' they usually appear to the English economist to confound what is with what ought to be. The assumption that egoism ought to be universal—that the universal prevalence of self-interest leads necessarily to the best possible economic order—has never been made by leading English writers; and it is an assumption with which they generally conceive themselves in no way concerned—in that part, at least, of the science which deals with distribution. It is the actual prevalence of self-interest in ordinary exchanges of products and services which constitutes their fundamental assumption.

But I admit that this reply does not end the controversy. The critic may rejoin that, if egoism is not what it ought to be, the tranquil way in which the economist treats it as universally predominant is objectionable, as tending to give dangerous encouragement to the baser side of human nature. And, secondly, he may deny that self-interest actually has any such predominance as English economists assume; hence, he may argue, their fundamental assumption must lead to serious errors in the analysis and forecast of actual facts.

The first of these points I should concede to some extent. If we regarded it as blameworthy that a man should, under ordinary circumstances, try to get the highest price for any commodity he sells, and give the lowest for what he buys, then, though the analysis of economic facts, as they exist in the present selfish and wicked world, might still be conducted on the present method, I certainly think its results ought to be—and would be—expounded in a different tone. I should say, therefore, that our economists generally do not hold to be censurable, in a broad and general way, the self-regard which they assume as normal. I conceive, however, that this view is commonly held with the following important qualifications.

Firstly, it is not implied that the right of free exchange ought not to be legally limited in respect of certain special commodities. Thus, when it is urged by statesmen or philanthropists that the sale of opium, or brandy, or lottery-tickets, or children's labour ought to be prohibited or placed under certain restrictions, the political economist, as such, is not to be regarded as holding a brief on the other side—at most he only throws the *onus probandi* on those who advocate interference, adding perhaps a warning that the consequences of their measure may possibly be different from what they anticipate, owing to the play of ordinary self-regard working under the new conditions that they aim at imposing.

Secondly, it is not implied that similar limitations may not be effectively imposed by the force of moral opinion. It has, indeed, to be pointed out that morality, like law, may produce effects other than what are designed—*e.g.* that the discredit attaching to usury may cause the unhappy debtor to pay more instead of less for his inevitable loan, since the usurer has to be compensated for the social drawbacks

of his despised employment. But it does not follow that there are no cases in which this disadvantage has to be faced as the least of two evils.

Thirdly, the economist does not assume that his economic man is *always* buying in the cheapest and selling in the dearest market, and never rendering services to his fellow-creatures on any other terms. He does not lay down that the economic distribution which it is his business to analyse will not be supplemented to an indefinite extent by a distribution prompted by other motives:—indeed, it should be noted that the ordinary economic man is always understood to be busily providing for a wife and children; so that his dominant motive to industry is rather domestic interest than self-interest, strictly so-called. And it has never been supposed that outside his private business—or even in connection with it if occasion arises—a man will not spend labour and money for public objects, and give freely gratuitous services to friends, benefactors, and persons in special need or distress.

The political economists, it is true, have often felt called upon to criticise the proceedings of philanthropists; but those who have assumed in enunciating these criticisms a grave air of giving the results of abstruse scientific reasoning are partly to blame, I think, for having drawn on political economy a kind of odium which ought to have been thrown on the broader back of plain common sense. We may say, indeed, with special force of a great part of economic science what Huxley has said of science generally—that it is only 'organised common sense.' But it needs little organisation to show that the motives to industry and thrift are impaired by the indiscriminate relief of the idle and improvident; that you help men best by encouraging them to help themselves, by widening the opportunities for the display of energetic activity and enterprise, and diffusing the knowledge that will save it from being wasted, rather than by diminishing the inducements that stimulate it. To apprehend the truth of propositions like these, a man need not even have read a shilling handbook; and yet these commonplaces constitute the greater part of the 'hard-hearted economist's' criticism of sentimental philanthropy. If, indeed, the economist has gone on to say that therefore no efforts ought to be made to relieve distress, and raise those who have temporarily stumbled in the struggle for existence, or if he has prophesied failure to all larger attempts on the part of philanthropists to improve the condition of the classes at the base of the industrial pyramid—if, I say, an individual economist has here and there been found lecturing and prognosticating in this sweeping manner, he has only exemplified the common human tendency to dogmatise beyond the limits of his knowledge; and I trust the blame will not be laid on the science whose exacter methods he has deserted or misapplied.

The important question of method, then, at issue between the English economists and their German critics is not whether the play of the ordinary motives of self-interest ought to be limited and supplemented by the operation of other motives; but whether these other motives actually do, or can reasonably be expected to, operate in such a way as to destroy the general applicability of the method of economic analysis which assumes that each party to any free exchange will prefer his own interest to that of the other party. And in speaking of the German historical school as antagonists on this question, I ought to say that I refer only to what I may call their more aggressive left wing. With the more moderate claims of the historical method as set forth by the distinguished leader of the school, William Roscher, the English economists who maintain the tradition of Adam Smith and Ricardo have no sort of quarrel; and Roscher expressly disclaims any quarrel with them. He has sought, as he says, 'gratefully to avail himself' of the results of Ricardian analysis, and we can no less gratefully profit by the abundant historical researches that he has led and stimulated. It is no doubt true that our older economists often had an insufficient appreciation of the historical variations in economic conditions; and, in particular, did not adequately recognise the greater extent to which competition was limited or repressed by law or custom in states of society economically less advanced than our own. But for a generation there has been no serious dispute about this; nor has there ever been any fundamental disagreement between Ricardians and Roscherians as to the right method of studying the history of economic facts. The most deductive English economist has

never gone so far as to maintain that this can be constructed *à priori*, any more than any other history; and if a generation ago he was sometimes wont to dogmatise with insufficient information as to the causes of industrial changes and the economic effects of political measures in other ages and countries, he has grown wiser, like other persons, through the great development of historical study—and of what I may call the common historic sense of educated persons—which has taken place in the interval. Indeed, I think the danger now is rather that we should go into the opposite extreme, and not give sufficient attention to the more latent and complicated but very effective manner in which competition is found operating even in states of society where the barriers of custom are strongest.

But further, even as regards the present condition of industry in the more advanced countries, to which the theory of modern economic science primarily relates, there is, I conceive, no dispute as to the need of what is called a 'realistic' or 'inductive' method—*i.e.* as to the need of accurately ascertaining particular facts when we are inquiring into the particular causes of particular values, or of the shares of particular economic classes at any given place and time. All that the deductive reasonings of English economists supply is a method of analysing the phenomena and a statement of the general causes that govern them, and of the manner of their operation. In this analysis, no doubt, the assumption is fundamental that the individuals concerned in the actual determination of the economic quantities resulting from free exchange will aim, *ceteris paribus*, at getting the most they can for what they sell and giving the least they can for what they buy. And when we find the legitimacy of this assumption, and the scientific value of the analysis based upon it, broadly assailed by Hildebrand,[1] Knies,[2] and others, we are no doubt seriously concerned to meet their criticism.

For my own part, I can only say that, having searched their works with the interest and respect which are due to the indefatigable research and the scientific fertility of the German intellect, I am quite unable to discover what other scientific treatment of the general theory of distribution and exchange they propose to substitute for the treatment which they sweepingly criticise. I cannot perceive that their higher view of man as a moral, sympathetic, public-spirited being, habitually rising above the sordid huckstering considerations by which English economists assume him to be governed, has any material effect on their theory of the determination of economic quantities when it comes to be actually worked out. When Knies,[3] for instance, is discussing the nature and functions of capital, money, and credit, or when he is arguing with more subtlety than success against the Ricardian doctrine of rent, we find that the capitalists and landlords, the lenders and borrowers, whose operations are contemplated, exhibit throughout the familiar features of the old economic man. So, again, when, in the Encyclopædia of Political Economy[4] recently published by this school, we examine the definitions of fundamental notions, or the explanation of prices, or the theory of distribution, we meet, indeed, with some interesting variations on the old doctrines, but we find everywhere the old economic motives assumed and the old method unhesitatingly applied. The proof of the pudding, as the proverb says, is in the eating; but our historical friends make no attempt to set before us the new economic pudding which their large phrases seemed to promise. It is only the old pudding with a little more ethical sauce and a little more garnish of historical illustrations.

In saying this I should be sorry to seem to underrate the debt that economic science owes to the labours of the school now dominant in Germany. Much of the positive work that they have produced is in its way excellent; even their criticism of the older method has been, in my opinion, most useful; and if I complain that they have by no means done what they announced, with some flourish of trumpets,

[1] See two papers on 'Die gegenwärtige Aufgabe der Wissenschaft der politischen Oekonomie,' in the first volume (1863) of Hildebrand's *Jahrbuch für National-Oekonomie u. Statistik*, p. 5ff. and p. 137ff.: especially his criticism of J. S. Mill (p. 23), quoted with approval by Schönberg in the introduction to his *Handbuch*.

[4] See Schönberg's *Handbuch*, iv. v. and xi.

that they were going to do, it is chiefly because their exaggerated phrases have led critics of a looser sort to misunderstand and misrepresent the recent progress and actual condition of economic thought. I fully recognise that the elaborate and careful study of economic facts in all departments, which the historical school has encouraged and carried out, is an indispensable aid to the due development of general economic theory. In all abstract economic reasoning which aims at quantitative precision, there is necessarily a hypothetical element; the facts to which the reasonings relate are not contemplated in their actual complexity, but in an artificially simplified form; if, therefore, the reasoning is not accompanied and checked by a careful study of facts, the required simplification may easily go too far or be inappropriate in kind, so that the hypothetical element of the reasoning is increased to an extent which prevents the result from having any practical value. And this danger is enhanced by the great, though generally gradual, changes in economic facts which accompany or constitute industrial development. Thus, for instance, a theoretical investigation of the purchasing power of money, which assumes for simplicity that coin and bank-notes form the sole medium of exchange, might easily lead to serious practical errors in the existing condition of industry; and a theory of capital which ignores the great and growing preponderance of auxiliary over remuneratory capital is liable to be similarly delusive. The general study of economic history is important as calling attention to this source of error: but for effective protection against it we must look to that patient and systematic development of statistical enquiry, which it is one of our main functions here to watch and to foster.

I must observe, however, that the historical economists are apt to insist too one-sidedly on the progress in economic theory attained by studying the industrial organisation of society in different stages of its development; they do not sufficiently recognise that other kind of progress which consists in conceiving more clearly, accurately, and consistently, the fundamental facts that remain without material change. But this latter kind of progress is very palpable to one who traces back the history of economic doctrines. Indeed, if our active controversy on principles and method has led anyone to think that political economists are always wrangling, and never establishing anything, he may easily correct this impression by turning to the older writers, and noting the confusions they make on points that are now clear to all instructed persons, and the inferences they unhesitatingly draw, which all would now admit to be in whole or in part erroneous. And by the 'older writers' I do not mean merely those who lived before Adam Smith: what I have just said is no less true of the 'Wealth of Nations' and its most distinguished successors. A tiro can now see the fallacy of Adam Smith's statement, that 'labour never varying in its own value' is a 'universal' and 'accurate standard of the exchangeable value of all commodities at all times and places'; the staunchest Ricardian would refuse to follow his master in maintaining that a tax on corn would cause labourers 'no other inconvenience than that which they would suffer from any other mode of taxation'; the most faithful disciple of J. S. Mill would not fall into the confusion between 'interest' and 'profit' which seriously impairs the value of important parts of his discussions. Much progress, I doubt not, still remains to be made, by steadily continuing that labour of reflective analysis through which our conception of fundamental economic facts has grown continually fuller and more exact; but no one who examines impartially the writings of our most eminent predecessors can ignore the progress that has already been made.

I now pass to consider another old charge against political economists, which has been recently revived: the charge of confining their attention too much to the special group of phenomena with which they are primarily concerned, and neglecting the relations of these to other social facts. There have, no doubt, been writers—Senior is, perhaps, the most important—in whom such neglect was deliberate and systematic; but their peculiar view of economic method has long ceased to have much influence on current thought; and I hardly think that political economists are now more open to the charge of systematic narrowness than any other set of students who do not 'take all knowledge for their province,' but accept the limitations which the present state of research imposes as the inevitable condi-

tion of thorough work in any department. And so far as the charge hits a real defect, I doubt whether vague generalities about the 'consensus of the different functions of the social organism,' and the impossibility of 'isolating the study of one organ from that of the rest,' will be found of much practical use in correcting the defect; since the relations of other social phenomena to those which primarily concern the economist vary indefinitely in closeness and importance; so that the question how far it is needful to investigate them is one which has to be answered very differently in relation to different economic enquiries. Thus, in considering generally the first subject of Adam Smith's investigation—'the causes of the improvement in the productive powers of labour'—the importance of a healthy condition of social morality must not be overlooked; but it is not therefore the economist's duty to study in detail the doctrine or discipline of the different Christian churches: while any reference he may make to the history of the Fine Arts will obviously be still more remote and brief. If, however, we are considering historically the causes that have affected the interest of capital, the views of Christian theologians with regard to usury will require careful attention; if, again, we are investigating the share taken by a particular community in the international organisation of industry, the higher average of artistic sensibility among its members may be a consideration deserving of notice—as in the case of France.

Or again, we may illustrate the different degrees in which economic science is connected with different departments of social fact by comparing the chief classes of statistics with which this Section has concerned itself. Some of the most important of these—such as the statistics of taxation, trade, railways, land-tenure and the like, and a great part of the statistics of population—obviously supply the indispensable premisses of much of the economist's reasoning, so far as it aims at being precise and particular, and the indispensable verification of many of his conclusions. In other cases again, as, for instance, the great departments of sanitary and educational statistics, the interest of the economist is more general and limited: for though both sanitation and education have important bearings on the productiveness of national labour, the details of the organisation for promoting either end lie in the main beyond the scope of his investigation; while he has manifestly still less to do with criminal statistics, military and naval statistics, and several other species of social facts which governmental or private agencies now enable us to ascertain with approximate quantitative exactness.

At this point, however, our critics will probably say that it is not so much a knowledge of the separate relations of different groups of social phenomena that the political economist lacks, but rather a true conception of the social organism as a whole, and of the fundamental laws of its development; he does not recognise that his study can only be legitimately or profitably pursued as a duly subordinated branch of the general science of sociology. This view was strongly urged by Mr. Ingram in his presidential address to this Section seven years ago in Dublin [1]; and it was enforced by pointing contemptuously to the limited function which well-instructed economists at the present day are careful to allot to their science in the settlement of practical questions. When we explain, with Cairnes, that political economy furnishes certain data that go towards the formation of a sound opinion on such questions, but does not undertake to pronounce a final judgment on them, we are told that this 'systematic indifferentism amounts to an entire paralysis of political economy as a social power'; and that the time has come for it to make way for, or be absorbed into, the 'scientific sociology' which is now in the field, and certainly seems ready to offer statesmen the dogmatic, comprehensive, and complete practical guidance which mere economic science confesses itself inadequate to supply.

It appears to me that Mr. Ingram and his friends somewhat mistake the point that they have to prove. It is not necessary to show that if we could ascertain from the past history of human society the fundamental laws of social evolution as a whole, so that we could accurately forecast the main features of the future state

[1] It has been recently expressed again, with no less emphasis, in Mr. Ingram's article on 'Political Economy,' in the nineteenth volume of the *Encyclopædia Britannica*.

with which our present social world is pregnant—it is not needful, I say, to show that the science which gave this foresight would be of the highest value to a statesman, and would absorb or dominate our present political economy. What has to be proved is that this supremely important knowledge is within our grasp; that the sociology which professes this prevision is really an established science. To deny this may perhaps seem presumptuous, in view of the voluminous works that we possess on the subject, which it would be quite out of place for me to attempt to criticise methodically on the present occasion. Fortunately, however, such methodical criticism is not required to justify my negative conclusion: since there are two simple tests of the real establishment of a science—emphatically recognised by Comte in his discussion of this very subject—which can be quickly and decisively applied to the claims of existing sociology. These tests may be characterised as (1) Consensus or Continuity and (2) Prevision. The former I will explain in Comte's own words:—'When we find that recent works, instead of being the result and development of what has gone before, have a character as personal as that of their authors, and bring the most fundamental ideas into question'—then, says Comte, we may be sure we are not dealing with any doctrine deserving the name of positive science. Now, if we compare the most elaborate and ambitious treatises on sociology, of which there happens to be one in each of the three leading scientific languages—Comte's 'Politique Positive,' Spencer's 'Sociology,' and Schäffle's 'Bau und Leben des socialen Körpers,'—we see at once that they exhibit the most complete and conspicuous absence of agreement or continuity in their treatment of the fundamental questions of social evolution.

Take, for example, the question of the future of religion. No thoughtful person can overlook the importance of religion as an element of man's social existence; nor do the sociologists to whom I have referred fail to recognise it. But if we inquire after the characteristics of the religion of which their science leads them to foresee the coming prevalence, they give with nearly equal confidence answers as divergent as can be conceived. Schäffle cannot comprehend that the place of the great Christian Churches can be taken by anything but a purified form of Christianity; Spencer contemplates complacently the reduction of religious thought and sentiment to a perfectly indefinite consciousness of an Unknowable and the emotion that accompanies this peculiar intellectual exercise; while Comte has no doubt that the whole history of religion—which, as he says, 'should resume the entire history of human development'—has been leading up to the worship of the Great Being, Humanity, personified domestically for each normal male individual by his nearest female relatives. It would certainly seem that the science which allows these discrepancies in its chief expositors must be still in its infancy. And when we go on to ask how these divergent forecasts of the future are scientifically deduced from the study of the past evolution of mankind, we are irresistibly reminded of the old epigram as to the relation of certain theological controversialists to the Bible:

Hic liber est in quo quærit sua dogmata quisque,
Invenit et pariter dogmata quisque sua.

I do not doubt that our sociologists are sincere in setting before us their conception of the coming social state as the last term of a series of which the law has been discovered by patient historical study; but when we look closely into their work it becomes only too evident that each philosopher has constructed on the basis of personal feeling and experience his ideal future in which our present social deficiencies are to be remedied and that the process by which history is arranged in steps pointing towards his Utopia bears not the faintest resemblance to a scientific demonstration.

This is equally evident when we turn from religion to industry, and examine the forecasts of industrial development offered to the statesman in the name of scientific sociology as a substitute for the discarded calculations of the mere economist. With equal confidence, history is represented as leading up, now to the naïve and unqualified individualism of Spencer, now to the carefully guarded and elaborated socialism of Schäffle, now to Comte's dream of securing seven-roomed houses for all working men—with other comforts to correspond—solely by the im-

pressive moral precepts of his philosophic priests. Guidance, truly, is here enough and to spare; but how is the bewildered statesman to select his guidance when his sociological doctors exhibit this portentous disagreement?

Nor is it only that they adopt diametrically opposite conclusions: we find that each adopts his conclusion with the most serene and complete indifference to the line of historical reasoning on which his brother sociologist relies. Schäffle, *e.g.*, appears not to have the least inkling of the array of facts which have convinced Spencer that the recent movement towards increased industrial intervention of government in Germany and England is causally connected with the contemporaneous recrudescence of 'militancy' in the two countries. And similarly, when Spencer explains how, under a régime of private property and free contract, there is necessarily a 'correct apportioning of reward to merit,' so that each worker 'obtains as much benefit as his efforts are equivalent to—no more and no less,' he exhibits a total ignorance of the crushing refutation which, according to Schäffle, this individualistic fallacy has received at the hands of socialism. The tendency of free competition to annihilate itself, and give birth to monopolies exercised against the common interest for the private advantage of the monopolists; the crushing inequality of industrial opportunities, which the legal equality and freedom of modern society has no apparent tendency to correct; the impossibility of remunerating by private sale of commodities some most important services to the community; the unforeseen fluctuations of supply and demand which a world-wide organisation of industry brings with it, liable to inflict, to an increasing extent, undeserved economic ruin upon large groups of industrious workers; the waste incident to the competitive system, through profuse and ostentatious advertisements, needless multiplication of middle-men, inevitable non-employment, or half-employment, of many competitors; the demoralisation, worse than waste, due to the reckless or fradulent promotion of joint-stock companies, and to the gambling rife in the great markets, and tending more and more to spread over the whole area of production —such points as these are unnoticed in the broad view which our English sociologist takes of the modern industrial society gradually emancipating itself from militancy: it never enters his head that they can have anything to do with causing the movement towards socialism to which his German *confrère* has yielded.[1]

However, whether Spencer or Schäffle is a true prophet—whether the decay of war will bring us to a more complete individualism, or whether the increasing scale of the organisation of industry and its increasingly marked deficiencies are preparing the way for socialism—cannot certainly be known before a date more or less distant. But as Comte's sociological treatise was written a generation ago, we are fortunately able to bring his very definite predictions and counsels to the test of accomplished facts. In 1854 he announced that the transition which was to terminate the Western Revolution would be organised from Paris, the 'religious metropolis of regenerate humanity,' where an 'irreversible dictatorship' had just been established, within the space of a generation. In the initial phase of the transition, which ought to last about seven years, perfect freedom of the press would 'rapidly extinguish journalism,' owing to the 'inability of the journal to compete with the placard.' By a 'judicious use of placards, with a few occasional pamphlets,' Positivism would regenerate public opinion. The budget of the clergy, the University of France, the Academy of Sciences must be suppressed, and the proximate abolition of copyright announced. By these moderate measures Louis Napoleon's irreversible dictatorship might be 'perfected and consolidated,' so that the dictator might assume complete legislative power, reducing the Representative Assembly—which would sit once in three years—to the purely financial function of voting the budget. In the second phase of the transition, which should last about five years, the 'dictatorial government now unquestionably progressive,' would suppress the French army, substituting a constabulary of 80,000 gendarmes. This would suffice to maintain order, internal and external, as the oppressive

[1] See Schäffle's 'Kritik der kapitalistischen Epoche,' in *Bau und Leben des socialen Körpers*, vol. iii. pp. 419–457.

military establishments of neighbouring states would everywhere fall as soon as France had put down her army. The dictator would then break up France into seventeen separate intendancies as a step towards the ultimate Positive régime, under which the peoples of Western Europe are to be distributed into seventy republics, comprising about 300,000 families each. The third and last phase of the transition, which should occupy about twenty-one years, might be expected to be opened by the voluntary abdication of the dictator in favour of a triumvirate, consisting probably of a banker to manage foreign affairs, an 'agricultural patrician' as minister of the interior, and a working man to take charge of the finances. Their names would be suggested by the High Priest of Humanity—indeed, Comte tells us that he had been 'working for several years at the choice of persons,' in order to be ready for this momentous nomination: for the immense influence which Positivist doctrine ought to have gained by this time would enable the political direction of France to be placed completely in the hands of Positivists. This triumvirate would transform the seventeen intendancies into separate republics: the *bourgeoisie* would then be gradually 'eliminated' by the extinction of *littérateurs*, lawyers, and small capitalists, so that society would pass easily into the final régime.[1]

I need not go on to this final régime: I have already given you more than enough of these extravagances; but it seemed important to show how completely the delusive belief that he had constructed the science of sociology could transform a philosopher of remarkable power and insight into the likeness of a crazy charlatan. I trust that our Association will take no step calculated to foster delusions of this kind. There is no reason to despair of the progress of general sociology; but I do not think that its development can be really promoted by shutting our eyes to its present very rudimentary condition. When the general science of society has solved the problems which it has as yet only managed to define more or less clearly—when for positive knowledge it can offer us something better than a mixture of vague and variously applied physiological analogies, imperfectly verified historical generalisations, and unwarranted political predictions—when it has succeeded in establishing on the basis of a really scientific induction its forecasts of social evolution—it will not require any formal admission to the discussions of this Section; its existence will be irresistibly felt throughout the range of the more special inquiries into different departments of social fact to which we have hitherto restricted ourselves. It is our business in the meantime to carry on our more limited and empirical studies of society in as scientific a manner as possible. Of the method of statistical investigation I have not presumed to speak, as I have not myself done any work of this kind, but have merely availed myself gratefully of the labours of others. But, even so, it has been impossible for me not to learn that to do this work in its entirety, as it ought to be done, requires scientific faculties of a high order. For duly discerning the various sources of error that impede the quantitative ascertainment of social facts, eliminating such error as far as possible, and allowing for it where it cannot be eliminated—still more for duly analysing differences and fluctuations in the social quantities ascertained, and distinguishing causal from accidental variations and correspondences—there is needed not only industry, patience, accuracy, but a perpetually alert and circumspect activity of the reasoning powers; nor is the statistician completely equipped for his task of discovering empirical laws unless he can effectively use the assistance of an abstract and difficult calculus of probabilities. It is satisfactory to think that there is every prospect of statistical investigations being carried on, in an increasingly comprehensive and systematic manner, throughout an ever widening range of civilised countries. The results of this development cannot fail to be important from the statesman's no less than the theorist's point of view: for though the statistician, as such, does not profess to guide public opinion on political questions, there can be no doubt—as Mr. Giffen has recently pointed out—that the knowledge attained by him tends to exercise on the general discussion of such questions an influence, on the whole, no less salutary than profound.

[1] These details are taken from Comte's *Système de Politique Positive*, vol. iv. chap. v.

2. *On the alleged Depression of Trade. By* Professor LEONE LEVI, *F.S.S.*

The paper criticised numerous essays upon which the author had been recently asked to adjudicate. The value of these essays did not consist in the discovery of any new method for the prevention or remedy of such depression—they did not expect that—but rather in their presenting a well-digested survey of the circumstances which preceded and the causes which produced the depression. There was nothing new, indeed, in the occurrence of even a somewhat protracted depression of trade. Some have gone so far as to detect a connection between the solar surface and certain terrestrial phenomena, as between sunspots and the price of wheat. The causes of the present depression were variously stated by the different essayists. Among the causes mentioned are—the diminished production and consequent appreciation of gold; the heavy losses in agriculture consequent on several successive bad harvests, accompanied by competition of large foreign imports brought to this country at exceedingly low rates of freight; over-production in manufacture, shipping, iron, coal, in fact, in production of every kind, the effect of improved plant and machinery, as well as of larger amount and greater concentration of capital; heavy losses of national resources caused by numerous destructive wars, and the large war expenditure yearly incurred by the principal countries of Europe; extensive speculative investments utterly disappointing in their results; an excessive expenditure in alcoholic beverages and the improvidence of the working classes; the restrictive tariffs in many States which intercept the free course of commerce and condemn nations to suffer, either from the exclusion of necessary or useful commodities or from excessive monopoly prices; the cessation of great discoveries, and the revolution produced by the greater speed in communication. Among the remedies suggested for commerce and manufacture are—the introduction of better machinery and improved processes in manufacture; the opening of new channels of trade, and greater economy both in production and distribution; and for agriculture, a cheaper and safer system for the transfer of land, as well as greater stability of tenure. Only one essay out of fifty-eight was found to advocate fair-trade, and to bring forward reasons against the maintenance of our free-trade policy. A comparison had been made of the amount of trade in 1873 and 1883; but 1873 was an exceptional year. For a sound view of the condition of trade a longer period was necessary. If they divided the last twenty years into four quinquennial periods, they found that, measured per head of the population, and comparing 1865–69 with 1880-85, the imports show an increase of 19·57 per cent., and the exports of British produce and manufacture show an increase of 11·76 per cent., while there was an increase in the total trade at the rate of 19·64 per cent. The total trade of the United Kingdom, which in 1865–69 averaged 516,000,000*l.*, rose in 1880–84 to 707,000,000*l.* But, while the declared value of imports and exports is determined by the prices, the consuming power of the people was best seen by the quantities received or sent out. The shipping returns showed that, whilst in 1865–69 the tonnage of British and foreign vessels cleared at ports with cargoes only to foreign countries averaged 14,614,000 tons, in 1880–84 it averaged 27,673,000 tons. Whilst the population of the principal countries increased at the rate of 10 per cent. in ten years, our exports in value increased at the rate of upwards of 40 per cent., and in quantity at a still greater rate in twenty years. The best reason for low prices would be found in the increasing production of different articles, the improved facilities of communication, lower freight, &c. There are still a few, he trusted only a very few, who lamented our increasing dependence on foreign countries for the necessaries of life, and who contended that the excessive balance of imports over exports indicated an enormous indebtedness to foreign countries or an absolute loss in our exchanges. In their opinion, with a view to the greater employment of the labouring classes at home, and as a matter of simple fairness to the people of this country, we should prohibit or restrict the imports of manufactured and even semi-manufactured articles, including, for instance, wheat-flour. Nay, more, what they advocate is to do unto others what they do unto us, meet prohibition with prohibition, high duties with high duties, and bounties with countervailing duties. It should be re-

membered, however, that the increasing imports of articles of food are on the one hand the consequence of the improved condition of the people, which enables them to eat and drink more than they were able to do in former years, and on the other hand the result of natural conditions which determine and limit the productiveness of the soil in the United Kingdom—a fact which we cannot remedy, and which we can only meet by the importation of foreign produce. We would commit the greatest possible error were we to attempt to benefit the working classes by the restriction of the imports and by the reduction of the amount of foreign trade: any restraint of that character having the effect of benefiting the few at the expense of the many. Doubtless we must lament the prevalence of erroneous economic principles in several countries; financial exigencies, and more especially the influence of interested parties in the Government and in the Legislature, have retarded the practical adoption of principles admitted to be sound and unquestionable. But no political economist anywhere has ever spoken a word in favour of either restrictive tariffs, bounties, or prohibitions. The general condition of trade is certainly considerably altered, and is much more precarious than it was fifteen or twenty years ago. First of all, an increasing competition exists at home and abroad, not only among producers, but among distributors. At this moment Chinese and Japanese merchants compete with British merchants in the trade of the East, just as French and German manufacturers are striving to wrest from the British manufacturers a share in the supply of the textile and other manufactures. Nor have a few capitalists any longer a monopoly of trade. By the extension of joint-stock companies with limited liability, hundreds of millions find their way into trade and public works, and these companies being content with realising a small percentage of profits, private merchants must consent to work on equal terms. By the greater vigilance of workmen, manufacturers have no longer in their power to maintain wages at as low a rate as possible. They are made to divide with the workmen in the shape of higher wages a full portion of their profits. And the advantages which leading merchants once possessed from their extensive agencies are neutralised or lost by the promptitude with which everything is communicated to the world through the press, whilst electricity and steam have by their speedy or instantaneous movement greatly narrowed the field of speculation. Monometallism, or Bimetallism, has nothing to do with the depression of trade. Money is plentiful. What is wanted are a greater diffusion of comforts, and more confidence in political and social tranquillity. Altogether ill-founded are the complaints made against free-trade. Deeper causes than any changes in the commercial policy of this or of any country have produced the depression of trade so much complained of. If the Royal Commission lately appointed on the depression of trade, or any members of the same, are in any expectation that the facts which may be presented to them justify either the reimposition of the Corn Laws, or the introduction of differential duties in favour of the British Colonies and against foreign countries, or a prohibitive or restrictive tariff of imports, they will be grievously disappointed. I do not object to an inquiry. It will put an end to much idle talk. It will show on what foundation of sand fair-traders and protectionists are relying. The verdict of the nation has long been pronounced, and the Royal Commission summoned to, if possible, reverse the same will, like Balak of old, not only reject the appeal, but confirm it as irrevocable. Royal Commissions cannot improve trade. What we require is to open and not to shut the avenues of wealth. We are all deeply concerned in its increase all over the world. All nations depend on the abundance of their harvest from year to year. Let us pray that their garners may be full, affording all manner of store. Commerce will ever be the landmark of peace. Let us rebuke the thoughtless, the suicidal mania for a warlike policy; let us put a check to the ruinous maintenance of enormous armies. Britain need not fear competition, and there is no reason why her productions should be inferior to those of any other nation in solidity, taste, and economy. She possesses a cheap and abundant supply of coal and iron—she has a climate most conducive to continuous labour, and plenty of workers fully apt, would that they had always the will for their work. Wages are not higher here than in other countries, when we take into account the relative power exerted on matter. Nor

are the limited hours of labour a disadvantage, for labour saved is not lost. Britain has more capital than any other country, and nowhere the value of money is lower than in the United Kingdom. She has almost a monopoly of the carrying trade of the world, and she has the goodwill of a large and well-established custom. By all means let other nations advance in wealth and industry. There is room for all. Let us only trust for better times, and we may be quite sure that any rays of sunshine which may brighten our fellow-labourers in the field in any part of the world will likewise brighten and energise every branch of British industry.

3. *On the Variations of Price-Level since* 1850.[1]
By MICHAEL G. MULHALL, *F.S.S.*

Hitherto all efforts to ascertain the variations in the purchasing power of gold, especially since the year 1850, have been futile, because economists could not agree on the best method of fixing a level of prices. Some adopted index numbers, others arbitrarily laid down classifications of merchandise of primary or secondary necessity. But there is only one true way, namely, to take the current market value of the goods that are bought or consumed among nations, and compare the aggregate sum with the amount which the same quantity of goods would have cost at any former date with which it is sought to make a comparison.

The same quantities of products and merchandise consumed annually from 1881 to 1884 would have cost in previous periods, at the prices then ruling, as follows:—

—	Millions £ sterling				
	1841–50	1851–60	1861–70	1871–80	1881–84
Grain	1,419	1,724	1,658	1,547	1,326
Meat	560	628	661	747	830
Hardware	576	525	504	593	384
Dairy products	236	266	303	333	340
Cotton goods	386	335	484	346	302
Woollen goods	263	245	280	268	223
Timber	428	338	338	301	273
Coal	224	241	241	241	189
Leather	218	202	212	188	184
Potatoes	115	125	154	164	181
Wine	86	105	111	111	130
Raw Cotton	76	85	183	101	87
Wool	160	145	125	97	83
Books	120	115	105	87	79
Silks	68	82	104	88	73
Linens, &c.	77	74	78	74	70
Sugar	106	100	106	84	61
Coffee	23	30	38	50	42
Tobacco	29	44	53	38	37
Tea	16	20	24	21	16
Total	5,186	5,429	5,762	5,479	4,910

The above twenty items comprise 90 per cent. of all human industries, as regards products or manufactures, and therefore enable us to arrive at the exact variations of price-level for the whole world, that is the rise or fall in the purchasing power of gold since 1850. The result is as follows:—

Years		Years	
1841–50	100·0	1871–80	105·7
1851–60	104·7	1881–84	94·7
1861–70	111·1		

[1] See *History of Prices since* 1850, by the same author (Longmans & Co.), 1885.

We find, therefore, a fall of $5\frac{1}{4}$ per cent. from the price-level of the decade ending 1850, or nearly 15 per cent. from that of 1861–70. This is much less than people in England generally suppose, because it is the fault of Englishmen to limit their scope of observation to this island, when, by looking around at other nations, we might be better enabled to form a correct judgment.

It is remarkable that if we separate agricultural (including pastoral) products from manufactures, we find the former have risen 11 per cent., the latter fallen 25 per cent., since 1850. The present volume of the world's products at previous prices would have represented the following values:—

Years	Millions £		Ratio	
	Agriculture	Manufactures	Agriculture	Manufactures
1841–50 . . .	2,826	2,360	100	100
1851–60 . . .	3,272	2,157	116	91
1861–70 . . .	3,416	2,346	121	99
1871–80 . . .	3,293	2,186	117	92
1881–84 . . .	3,133	1,777	111	75

Therefore, fifteen shillings will now buy as much manufactures as twenty in the years 1841–50, but in matters of food we should require twenty-two.

As regards the causes which led to the fall in price-level I have nothing now to say, my present purpose having simply been to fix precisely the relative value of gold as compared with merchandise in the thirty-five years that have elapsed since the great discoveries of the precious metal in California and Australia.

FRIDAY, SEPTEMBER 11.

The following Papers were read:—

1. *On the Municipalisation of the Land.* *By* Sir George Campbell, *K.C.S.I., M.P.*

It need hardly be said that the municipalisation of the land is no new-fangled idea, but one of the oldest of human institutions. From the earliest times of which we have historical knowledge the communal tenure was universal both in Europe and in Asia, and in most countries it prevails to the present day. We are specially familiar with it in India.

Such a tenure is by no means inconsistent with individual property; on the contrary, individual possession of the arable land is one of the features of the system. In pastoral times tribes may have held large tracts in actual community; but, as soon as agriculture is introduced, there is always a partition for that purpose. It is true that the jealousy of inequality and unfairness was such that the early law of the village communes required the periodical redistribution of the land according to the recorded ancestral shares, but our experience in India is (and it is the same in Europe) that in course of time this also becomes obsolete; the arable land becomes permanent individual property subject to certain superior and reversionary rights of the community, as also do the sites of dwellings and the curtilages attached, while a tract of grazing and certain rights of wood and water, &c., remain common to the community.

It is for want, I think, of appreciation and understanding of the true communal tenure that in Ireland and elsewhere it seems to be supposed that there is an opposition and antagonism between what is called nationalisation of the land and peasant proprietorship. On the contrary, under the communal system the superior right of the community and the private right to individual holdings exist together,

and are, in fact, the complement and support of one another. It is the old story of the bundle of sticks—united they are strong, separated they are weak.

In this country the old communal system has for the most part gone, and it would be very difficult to replace it throughout the country, but in most self-governing towns it long lingered. In Scotland most of our Royal burghs had considerable land—the 'common good'—till it was alienated by the corrupt Town Councils of former days. And to this day in Scotland the town is usually the superior or ground landlord of the proper municipal area, individual sites being held under the town on 'burgage' tenure. Towns have now extended far beyond those old municipal limits, and can only find room by taking sites from the surrounding landlords. Not only is there an enormous increment of the value of this circumjacent land, unearned by the proprietors and due to the industry of the townspeople, but this land is also subjected to a monopoly value far beyond what it would fetch if freely thrown on the market. Land, which will in no other way fetch 1*l.* or 2*l.* per acre, is not given for building purposes till the pressure is so great that 20*l.*, 30*l.*, or 40*l.* per annum is paid. Hence comes the deprivation of gardens, overcrowding, and many evils which have been recently depicted by the Royal Commission on the Housing of the Poor.

In Ireland and the Highlands of Scotland it will probably be found that the system of very small agricultural holdings requires some communal organisation for many purposes, but I will not enter on that here. Admitting that in the greater part of Britain agriculture has reached a stage which could make agricultural municipalisation on a very large scale very difficult at present, I address myself now to the municipalisation of the land near towns and populous places. The population of this country is now so great and the supply of food from all quarters so enormous that very much of our land is more important from the point of view of health and recreation than for the raising of corn.

Some of us may be inclined to think that no good comes out of Ireland. Yet I believe that nowadays some things are conceded as an indulgence to Ireland which are afterwards found not to be altogether inapplicable to this country. The 'Labourers' Dwellings (Ireland) Act' was looked on with much suspicion. But now, as the result of the report of the Royal Commission on the Housing of the Poor, a new departure in the same direction has been taken in Britain by the Act for the Housing of the Working Classes, which has just passed the Legislature. It contains an important provision enabling town and rural authorities to take up lands, subdivide them, and let them out for cottages and gardens in plots not exceeding half an acre each. That is, I think, a first and very large step towards what I call the municipalisation of the land. Something might also be done to settle labourers on larger crofts in the country, but I leave that for the present.

No one who has paid any attention to the subject can doubt the extreme importance and necessity of giving room to our working classes, both from a sanitary and from a moral point of view. The deprivation of gardens and back yards, the crowding into unhealthy tenements, not only deteriorates the race physically, but drives the men into the public house, the women into dirt and disrepute, the children into the gutter. More room is absolutely required, and more room means more land in decentralised positions connected with the centre by the facilities which modern means supply. If the rent of building land is 30*l.* or 40*l.* or more per acre, gardens and yards are impossible to the working classes; and, therefore, more room is only possible with cheaper land. It would be very difficult, and tend towards socialism and want of self-reliance that the public authority should not only find the land, but build, equip, and maintain the houses on a large scale. What is required is such a tenure that individuals may do so much. At the same time, in crowded communities it is right to maintain a sufficient control over individuals, so as to ensure that one man may so use his own as not to injure others. And it is well that a public revenue should be derived from the land rather than from excessive taxation.

Not only is the monopoly price of land near towns excessive, but the tenure is unsatisfactory. The English system of terminable building leases is one against which modern feeling rebels, and if there is sometimes some advantage in the

regulating power of the ground landlord, it is capricious and uncertain. In Scotland the system of perpetual feus has great advantages; but even there landlords are in many places introducing terminable leases after the English pattern, but shortening their duration. More than that, it is the case not only in the Highlands, but beyond the Highlands, that houses are built by tenants without any tenure at all on mere holdings from year to year. This is especially the case in the great and progressive county of Aberdeen. The smaller farms and crofts with the buildings on them are usually held on this slender title. And great fishing villages all round the coast, inhabited by a very energetic, prosperous, and progressive race, are held equally without any security. The houses are entirely built by the fishermen. They pay for every stick and every stone, yet they are liable to be turned out at the end of every year at the will of the landlord. In and about the prosperous sanitorium of Braemar the old houses have no better tenure, and I am told that on one of the two great estates there for the building of valuable villas no better tenure can be obtained than leases of between thirty and forty years.

The papers presented to Parliament a little time ago regarding the house-tenure of foreign countries show that abroad individual ownership of the occupier is far more common than with us, and the sites are altogether held on a better tenure. But then everywhere in those countries the municipalities, towns, and communes have a much greater control in the common interest, and exercise it much more actively and effectively. That, then, is the model to which I would look in any municipalisation of land—*i.e.*, to vest the superior right of the ground landlord, as it were, in the municipality, with sufficient power of regulation and control, and under the municipality to let out plots for buildings and gardens on a title not altogether absolute, being subject to certain limitations, conditions, and control, but still secure and liable to interference of the public authority only, and not to the caprice of any individual. There would be, in fact, a new burgage tenure something like Scotch feus, with the municipality as superior landlord, and the feu rents would be payable to the municipality.

On a system such as this, well-managed municipalities might, I think, advantageously take up a great deal of land in their neighbourhood, so as to allow of a large extension and secure the benefit of the growing value as the town extends. Some supervision of a central authority may be necessary, but not so much as is imposed by the recent Act. The action of local bodies is there hampered by so many checks and counter-checks that happily the operation of the provisions which I have mentioned may be very limited. Still, the principle of municipalisation is very clearly there, and if the law were worked in a very liberal spirit, scarcely anything more might be required to attain such a municipalisation as I desire, if only the price to be paid for the land could be well settled. *There* is the rub. The fact is, that there are two prices—the price which the land will fetch when thrown on the market and the price which is obtained in driblets, in virtue of a monopoly, by closing the market and saying you shall have nothing till you pay an exorbitant price. The time may come when the divine right of the landlord to the urban increment unearned by him may be called in question. But in present circumstances, it is enough to claim that the price should be, not the arbitrary monopoly price, but the price which a willing seller would get from a willing buyer at the time. Municipalities should be entitled to claim land conveniently situated for extension, and not specially appropriated for demesnes on those terms. With reasonable good management they should sustain no pecuniary loss on such transactions.

If such a system were well introduced, then we may well believe that our crowded and unwholesome towns would expand into pleasant suburbs, with rows of cottages and gardens, such as we see in America and elsewhere, served by tramways, and the homes of an industrious and healthy people, combining their trades with gardens and small crofts, in which, rather than in the public houses, they would spend their spare time. Labour would be combined with recreation, intelligence, good society, and domestic virtues. We should arrive at the true dignity of labour, and avert many evils and many dangers.

2. *The Agriculture of Aberdeenshire.* *By* Colonel INNES.

The paper was mainly occupied by the agriculture of Aberdeenshire as a meat-producing industry, and as typical of the agriculture of the north-east counties of Aberdeenshire.

1. It traced how the export of fat cattle and dead meat for the southern markets by steamer and rail became the staple product of the agriculture of Aberdeenshire.

2. The change which is taking place in this product of fat cattle is, that the stock reared in the county is no longer sufficient to supply the store cattle for fattening, and that an increasing proportion of stores have to be imported.

3. The increasing competition which the meat produced in Aberdeenshire is encountering in the southern markets from foreign fat cattle and dead meat.

4. The remedy suggested. The importation of foreign store cattle to be fattened. The employment of imported cattle food.

5. The anticipated advantages are, (1) that the largely increased production of meat within the same agricultural area will be more profitable, (2) that the supply of the southern markets with meat, by importation of store-cattle, and feeding at home, instead of by importing foreign meat, will add to the fertility of the soil by the consumption of large quantities of imported food; (3) it will at the same time add to the resources of various industries, and to the food of the poorer classes by increased supply of the hides, tallow, and offals.

---

3. *The Agricultural Situation.*[1]
By Professor W. FREAM, *B.Sc., F.L.S., F.G.S.*

During the year there has been a sharp and decisive fall in the value of all kinds of agricultural produce. Though this has benefited the poorer classes it has proved most lucrative to the retail dealers in bread and in meat, for the decrease in the cost of these articles to the consumer exhibits an altogether inadequate ratio to the decline in their value to the producer.

The best English wheat has been sold for as little as 30*s.* per imperial quarter, which is the lowest price on record, the lowest price touched during the preceding thirty years having been 37*s.* 7*d.* in 1879, whereas the average price since last year's harvest has been about 33*s.* The fall in the price of wheat is partly attributable to the abundant harvest of 1884, when the yield of wheat was so large that the import of foreign wheat was less than in any year since 1876, and was 17 million cwts. less than in 1883, the shipping trade suffering severely in consequence. In the second week of March last barley and wheat were officially returned as of the same value, namely, 31*s.* 3*d.* per imperial quarter.

Pedigree cattle have undergone a very serious depreciation in value, and in many cases sheep have fallen to half the price they commanded two years ago.

Dairy farming, the last stronghold as it were of our declining agriculture, has been attacked in its most sensitive points, namely, the values of butter and cheese. Butter declined from 20 to 30 per cent. on the quotations of the previous year, and cheese from 20 to 40 per cent. on the preceding year's prices. In August the Cheshire cheese market fairly collapsed.

British farming was probably never in a gloomier condition, for it is not one branch alone but all that are now experiencing depression. Farmers will this year incur enormous financial losses, and it is difficult to discover how, in many cases, rents will be paid.

Taking the United Kingdom as a whole, it appears that during the decade from 1874 to 1884, there was a falling off in the area of arable land of 1,288,413 acres. Simultaneously, the area in permanent pasture increased by 1,936,790 acres. It would seem a startling statement to make that the British Isles are gradually going out of cultivation, and yet it appears that whereas in 1874 the areas under

[1] Published *in extenso* in the *Aberdeen Journal*, and in various agricultural journals.

arable cultivation and permanent pasture were practically equal (23,462,184 and 23,680,416 acres respectively), in 1884 they differed by nearly 3½ millions of acres (22,173,771 and 25,667,206 acres respectively). This change has been accompanied by a diminution of the rural population, though at the same time the total population underwent a marked increase. Thus, the census returns of 1871 gave the number of agricultural labourers in England and Wales as 962,348; ten years later the number had fallen to 870,798, a decrease of 91,550, representing a deficit of 9·5 per cent. on the number in 1871. The number of farmers in England and Wales underwent at the same time a similar decrease of about 10 per cent. Part, perhaps much, of the decrease in the farming population may be due to the more extended use of machinery, for the number of proprietors of agricultural machines let for hire, and of the attendants upon them, increased from 55 in 1851, to 1,441 in 1861, to 2,160 in 1871, and to 4,260 in 1881.

Perhaps the boldest course to take with regard to the state of agriculture is to look upon the depression as normal and permanent, and then to discover, if possible, how this new order of things may best be faced. A further fall in rents seems inevitable, unless landowners prefer the alternative of cultivating the land themselves. It is desirable that the producer and the consumer should be brought into closer relationship, for the middleman is thriving well at the expense of both. A perfect and rigid system of quarantine is desirable for the better protection of live stock from imported disease. Our home dairy practice requires to be raised to a distinctly higher level; at present Denmark is ahead of us in butter-making, and Canada in cheese-making. But in each country named the Government has fostered these industries by the advancement of technical education; our own Government is quite apathetic in the matter. The losses inflicted on crops and live stock by the ravages of insect, fungoid, and other pests, are stupendous, but this country possesses no organisation by means of which farmers could be instructed, warned, and advised on such matters. For these and allied purposes an efficiently equipped Department of Agriculture would prove of incalculable value.

After a brief description of the United States Department of Agriculture, and of the Department of Agriculture of Manitoba, the paper concluded by advocating the equipment of a Department of Agriculture for the United Kingdom, placed under the control of a responsible Minister of Agriculture, or of Agriculture and Commerce. Such a department could probably reach and influence the individual farmer in a manner which, for efficiency, no existing agency has been able to approach; it could diffuse valuable and necessary information of a simple and easily assimilable character, which would in time become embodied in the general practice of those by whom it would be received; it could collect and rapidly digest information from all the agricultural districts of the United Kingdom, and then issue, in the form of bulletins, timely warning on many matters which in the absence of such warning might have led to loss; and it could, under energetic and intelligent management, raise the entire agricultural industry of this kingdom to a higher level than it has ever yet attained. In the diminution of preventible losses alone such a department would prove invaluable. The agricultural functions now variously exercised by the Board of Trade, the Science and Art Department, and the Veterinary (or Agricultural) Department of the Privy Council, might well be transferred to it, but such a department would utterly fail of its object were it allowed to sink to the level of a mere record office. It should be an active, living, and progressive organisation, and the results it would then achieve would probably in a very few years amply justify the fact of its establishment and the cost of its maintenance.

---

4. *On recent Changes in Scottish Agriculture. By* Major P. G. Craigie.

The author claimed the right of Agriculture in its present depression to whatever aid science can afford. Intelligent use has been made in Scotland already of the teaching of scientific experiments. But before the help of any specific science is invoked in any new direction, it is indispensable that the facts and figures of the agricultural situation should be more clearly appreciated than they are by

most of those who offer advice to the practical farmer in his present straits. It must therefore be right to discuss first of all, in this Section of Economic Science and Statistics, what the position is, both relatively and absolutely, before any confident prescription can be offered for the ills of Scottish agriculture. To obtain some sure footing of a statistical nature, some means of contrasting the leading features of the agricultural situation as it presents itself in Scotland with the position of matters elsewhere, and some knowledge of wherein and to what extent the use made of the soil differs from the previous practice, is necessary if we are even to attempt to offer a diagnosis of the disease from which agriculture is suffering. This, and not any ambitious attempt to formulate hypothetical solutions of the land question, or to advise the Scottish farmer—proverbially the most shrewd of agriculturists—how to conduct his business, is the limited aim of the paper.

Partly owing to the character of the surface and partly to the form of our yearly returns, we know much less about the use and distribution of the soil in Scotland than in England. Only the proportions technically spoken of as 'under cultivation,' *i.e.* under some actual crop, bare fallow, or grass other than mountain or heath land, are accounted for annually. In England three-fourths of the surface come within this category, but only one-fourth in Scotland, so that for three acres out of every four in the latter case we have no information. Speaking more accurately, the measured surface of England, excluding Wales, is 32,597,000 acres, whereof 24,844,000 acres are regarded as cultivated; and the measured surface of Scotland is 19,467,000, whereof but 4,812,000 is in this sense cultivated. Barely 25 out of every 100 acres is thus reported on in Scotland, whereas in England it is only 25 out of every 100 that fails to be reported on. Yet it is at once evident from the live stock in the two countries that the official figures exclude much land used for the grazing of sheep, in some instances even of cattle and ponies. Our official tables therefore offering a contrast between the stock kept on each 100 cultivated acres in the two countries are misleading. It is the disregard of mountain pastures which makes it appear that England has of sheep 66, Wales 95, and Scotland 145 to each hundred acres. As a matter of fact, in the valuable statistics collected by the Highland and Agricultural Society in 1854, the 'sheepwalks' not entered in our annual statistics now, then covered 6,531,000 acres, or an area larger by one-third than all the cultivated land at present reported on. An enlargement of our statistics, which would supply information as to any changes in this branch of Scottish agriculture is therefore from every point of view desirable.

Excluding these mountain pastures, the small area of permanent pasture, one acre for three under the plough is noted, instead of one for one as in England. The large use of rotation grass which balances this feature is commented on and explained, a third, in place of a tenth as in England, of the cultivated area being thus utilised. The Scotch percentage of cereals in that area is 28·6 per cent. against 26·8 per cent. in England, but only 5 per cent. of the land in corn is used for wheat, as against 38 per cent. in England, oats occupying three acres out of every four.

Contrasts between the agricultural distribution of the soil thirty years ago, as shown by the Highland and Agricultural Society's statistics in 1855, and the official figures for 1869 and 1884, were then given, and tables were compiled exhibiting the parallel changes in England and in Ireland in the same interval. These showed that the arable area has increased in Scotland, though largely declining in England in the past fifteen years, permanent grass increasing very little in the North, while it shows a 20 per cent. increase in the South. Wheat-growing in Scotland, always a microscopic fraction of the national industry, had dropped from 191,300 acres in 1855 to 135,700 acres in 1869, and now to 68,700 acres in 1884, but the difference has gone in a large degree into other cereals, and it was specially noted that much of the decrease had occurred, not in consequence of the present depression, but before 1869. Tables and details showing for particular counties the changes over this period in greater detail were offered, and the characteristics of Scotch farming and the relation of the Scotch population to the small local wheat supply was noted.

The paper dealt with the question of suggested decline in cereal produce per

acre in Scotland. Contrasting the Highland Society's statistics in 1855, with recent inquiries, such as that undertaken by Major Craigie himself in 1882, and with the latest official figures the conclusion arrived at was that where wheat is still grown now, of course only on the best land, the yield is 31 or 32 bushels per acre against only $26\frac{1}{2}$ thirty years ago, barley yielding $35\frac{3}{4}$ against $32\frac{3}{4}$ at that date, while oats also advanced by several bushels, so that no grounds would appear to exist for the idea of a declining produce per acre.

After dealing with questions of the greatly altered money value of the gross outcome of the several crops—wheat, which brought in over 2,000,000*l.* in 1855, now contributing 455,000*l.* only to the aggregate receipts of the year, and both oats and barley fetching lower figures—an estimate of the acreable value at the present time was given. This the writer placed, taking all cereals into account, at 4*l.* 16*s.* per acre, as against 5*l.* 9*s.* 6*d.* thirty years ago.

Attention was then devoted to the changes in the live stock of Scottish farms—both generally and in detail by means of tables, and the parallel changes in England and Ireland were noted. Cattle had, on the whole, increased, and sheep, which were more numerous in 1869 than in 1855, are but slightly under the higher level now. This was contrasted with the English reduction of 17 per cent. in the flocks of that country. This was a matter specially worthy to be noted in view of the assertion that deer were taking the place of sheep. There were apparently a million more sheep in Scotland in 1869, than in 1855, and in the next 15 years up to 1884, the decline was only from 6,995,000 to 6,983,000, or 12,000 head; while in England in this period, the sheep were 3,394,000 fewer, and in Ireland 1,400,000 fewer. There was far less falling off in the Scottish flocks, than those of other European countries.

The question was then discussed as to what was the yearly out-turn of meat which Scottish farmers produce, and estimates varying from 160,000 to 140,000 tons yearly were mentioned and explained, and the sufficiency of the scale applied to the United Kingdom generally for the particular features of Scotch meat production was discussed. Scotland was shown to be, if a largely wheat-importing country, a distinctly meat-exporting one, and an opinion expressed that the breeding of stock yet more largely in Scotland would be advisable and was perfectly practicable.

SATURDAY, SEPTEMBER 12.

The following Papers were read :—

1. *On the International Forestry Exhibition.* *By* Dr. Crombie Brown.

The author said the richness and variety of the International Exhibition in Edinburgh, notwithstanding its deficiency, was fairly representative of British notions of arboriculture and forest economy; but the ignoring of sylviculture supplied an argument for the establishment of a National School of Forestry, in which might be taught and applied the advanced forest science of the day. It must be remembered that there was a great difference between arboriculture and sylviculture; and far-reaching results were to be expected from the scientific management of forests. There was, therefore, great need for a National School of Forestry. The great benefits which might reasonably be expected to follow therefrom were evident to everyone acquainted with the subject. It was chiefly the requirement of British colonies and lands similarly situated for the exploitation of forests that impressed him with the importance of having a National School of Forestry organised. The interest which our country had in the improvement of the forest economy of Great Britain supplied an equally urgent reason for such a measure being adopted. In every place where the British rule extended, except in India, there had been a ruinous neglect of forests. In South Africa alone millions of acres had been made desert from the destruction of the indigenous forests. This neglect

was a striking contrast to the interest taken in arboriculture and sylviculture in France, Prussia, Switzerland, and Russia. Colleges there were provided with a complete staff of accomplished professors, who trained youths of good birth to become State foresters. He did not see any immediate prospect of the establishment of a School of Forestry; attention, however, had been called to the matter in Parliament; and such a school must be established sooner or later. In Edinburgh a movement had been set afoot by the Marquis of Lothian and other gentlemen for raising 10,000*l.* for the exhibition of many valuable objects entrusted to them, and the establishment of a lectureship or professorship of forestry. The 10,000*l.*, however, was slow in coming in.[1]

2. *What is Capital?* *By* W. WESTGARTH.

The author alluded to the wide divergencies of view upon this question amongst leading economists. On behalf of commerce and banking he challenged the correctness of these views. Capital was usually defined by economists as consisting of things used in production, and as being only that part of wealth which is applied to produce further wealth. The same thing may be capital and not capital, according to the hands it is in. Thus, a manufacturer deals with capital, but not a shopkeeper, the former being a producer, but the latter only a distributor. Mr. Westgarth holds that this is only a conventional capital created in the minds of economists, and having no existence elsewhere. No doubt much confusion arose from the free and loose use, both in and out of business, of the term capital. Thus we had fixed capital, liability capital, and so on; but, holding the word to mean now universally the ready fund of business life, we ought, for clearness' sake, to avoid, in economic science, to give the term capital to anything else but this fund. No doubt the term capital had, originally and derivatively, the meaning expressed by 'fixed capital,' and the business fund might be viewed as an interloper in appropriating the name. But none the less we must accept facts. The interloper cannot now be dislodged, and we must not continue to call different things by one and the same name. What, then, is this capital fund? It is substantially the stocks of trading, called into existence, and maintained in existence, by the wants of trading or exchange. Every trader must have stock of his particular vocation, and this stock collectively is the society's capital. The merchandise and money and rolling-stock of a country's commerce constitute its capital fund. Money is only a particular form of merchandise. This capital fund increases or diminishes according to the circumstances of the trading, as requiring more or less stock. On the one hand is the constant tendency to economise capital so as to save the cost of holding it; on the other hand capital is ever increased by the constant effort to increase profit through extending the scale of business, and thus reducing relatively the expenses. We have thus the elements of the limitation or law of capital. For instance, the Suez Canal is cut in order, by the reduced time, to economise capital in shipping and cargo. But these economies themselves so increase the trading, that still more ships and cargoes than before are the result. The causes which economise or reduce capital are exceeded in effect by the causes which increase it; and thus, while increased profit is the object, increased capital is the concurrent result. We have here the elements of a 'law of capital.'

3. *On Methods of ascertaining Variations in the Rates of Birth, Death, and Marriage.* *By* F. Y. EDGEWORTH.

This paper is designed as a study in that branch of statistics which may be described as the method of eliminating chance by means of the mathematical theory of errors. In illustration of the general principle, the following example is discussed:—Suppose that the mean age at death of a hundred (or a thousand) total abstainers, taken from the general population above a certain age, is greater by a year or so than that of the general population, what presumption is there that

[1] Printed in *Forestry*, November 1885.

this difference is not accidental? It is shown that the answer depends upon a certain constant, or co-efficient, which might be calculated from life-tables. This constant enables us to find the probability that the mean age at death of a hundred (or a thousand) persons taken at random, would deviate to an assigned extent from the mean age at death of the general population. This all-important constant may be defined as one or other of the following correlated quantities: the *precision*, the *probable error*, the *modulus*, or (as the writer proposes to call the square of the modulus) the *fluctuation*.

Two problems in vital statistics, in the case of which the discovery of the requisite constant presents peculiar difficulties, form the special subject of this study.

I. Suppose out of a population, resident in the same place in the same year, there are taken at random several groups, and the death-rates calculated for each of those groups; according to what *modulus* would these figures fluctuate? It is required to elicit this answer from the Registrar-General's returns, which give only death-rates for different years and different places. The answer to this problem may be used to verify inferences concerning the relative unhealthiness of different occupations. But a wider utility attends the solution of the problem. The fact that the different methods by which it may be attacked lead to the same result is calculated to give us confidence in handling the mathematical instruments of statistics. We realise that to each class of phenomenon there appertains in general a tolerably constant co-efficient of fluctuation; which, having been obtained by observation, we shall be able to employ this datum of past experience to test future statistical inductions.

II. The second problem exemplified is to determine whether a given series of statistical returns indicates *progress*. Consider a set of figures representing the mortality of a certain population for several consecutive years. The theory of the *modulus* can determine whether an appearance of increase or decrease in these returns corresponds to a real difference in the conditions of life. The indications afforded by scientific method are apt to differ considerably from the guesswork of common sense.[1]

---

4. *On the Application of Biology to Economics.* *By* PATRICK GEDDES.

Since the progress of any order of ideas proceeds mainly from within, even heresies arising by a reversal of former beliefs, it is not to be wondered at if economists of all schools, orthodox or heterodox alike, are little attracted by the proposal to translate the propositions they debate from the time-honoured vernacular into the language of scientific specialists. Yet to point to this round-about way of simplifying matters is the object of the present paper. Not only, however, does biology owe much to economics—witness such a principle as the physiological division of labour—but the author of the 'Origin of Species' has traced its direct filiation to Malthus' theory of population.

A classic account of this relation is to be found in Mr. Spencer's well-known popular work 'On the Study of Sociology,' and the importance of the subject has often been insisted upon—witness Dr. Ingram's memorable presidential address of 1878, or his recent article 'Political Economy.' But as a recent reviewer scornfully asks, what have physics or biology to do with land-tenure, with taxation, the depreciation of silver, the rate of wages, the thousand and one problems of the economist?—but the reply is easy: what biology seeks to deal with are the fundamental conceptions of the subject, not their application to concrete details. Thus the biologist, while as yet at least wholly shrinking from interference with matters too high for him, will in no wise be restrained from claiming what the economist lumps as 'competition' as a form of the general struggle for existence, and seeking to analyse it, or, dissatisfied with the loose and popular notion of 'progress,' endeavouring to distinguish whether it means evolution or degeneration of population and their surroundings in each special case. When this is done the air becomes clearer: we see how, for instance, the dispute preceding the passing of

[1] Printed *in extenso* in the *Journal of the Statistical Society* for January, 1886.

the Factory Acts was not really at all a struggle between 'economic science' on the one hand and 'mere sentiment' on the other, but turned upon subordinating the lower ideal of physical economics—that of maximum production in given time—to the higher ideal of biological economics—that of maintenance and evolution of the population. Again, in the current dispute between individualist and socialist, we at once see that what the former has really taken his stand upon is simply the law of survival of the fittest, the principle of natural selection; while the socialist position has its essential base in the later but equally valid conception of the practicability of artificial selection. And thus for the biologist a line of research is clear—to unite and define these two vaguely-discerned positions, and to apply them to the interpretation of civilised society, as he already does not only for animals but for the lower races.

Nor is the general course of practical action less evident: the biologist must side with the individualist against the socialist in recognising that man can never shake himself wholly free from the iron grip of nature, yet, undiscouraged by this, since recognising the vast modifiability of life through its surroundings, must yet encourage the socialist in every rational effort to subordinate natural to artificial selection, and raise the struggle into the culture of existence.

But 'while philosophers are disputing about the government of men, hunger and love are performing the task.' From the physiological standpoint all functions are summed into those two—into nutrition and reproduction, into individual life and the reproduction of it. Thus the economist, whether taking sides for or against Malthus, cannot seriously deny that he has entered on a biological inquiry, and that one of fundamental importance to his own science. Now Malthus' principles are: (1) that population tends to outrun subsistence, but meets with checks in so doing; these checks being (2) *positive*, as war, famine, disease, &c.; or (3) *preventive* or moral. But the essential work of Darwin has lain in developing the first of these conceptions into that of the struggle for existence, as in recasting the second and third into natural and artificial selection respectively. Yet can it be urged that any economist has adequately applied these to theory or practice? Nay, more; perhaps the most valuable result of Mr. Spencer's biological labours lies in the demonstration of a limit law of population wider than those discerned by either Malthus or Darwin, namely that, other things equal, '*multiplication and individuation vary inversely*'; that is to say, the rate of reproduction of all living beings tends to be lowered as their individual development is raised, and conversely. Now, the practical outcomes of these three states of the theory of population are very different: for the economist who reads only Malthus there is no hope of curing the miseries due to over-population save by preventive checks of one sort or other; yet if he goes on to read Darwin, the advantage to the species of this struggle among the individuals becomes evident, and *laisser-faire* tends to resume the ascendant. Here in our day the discussion rests. Yet with what reason can they omit taking into account the law expounded by Spencer? And if this step be made, if the economist once really grasps the modern rather than the early theory of population, practical action at once assumes a new and higher aspect. For if individual life and rate of multiplication do indeed vary inversely, we have here the secret of the connection of poverty with progress—it lies primarily in the department of production, not that of distribution, let reformers of the latter say what they will; and the practical economists who would increase the well-being rather than the mere number of the population, must attempt a vast proportional increase in the industries which elevate life over those which merely maintain it, must make his ideal of progress for a long time lie rather in raising quality of production over mere quantity of it. Without keeping this clearly in view, the mere cheapening of food only multiplies poverty without increasing it, and our modest utopia of an adequate supply of penny dinners will but lead to an appalling demand for farthing ones. Yet reversed, the same iron law of wages, for such it is under its biological form, furnishes the economic justification of morals and of culture, the only yet sufficient hope of a general elevation of society.

MONDAY, SEPTEMBER 14.

The following Papers were read:—

1. *On the Use of Index Numbers in the Investigation of Trade Statistics. By* STEPHEN BOURNE, *F.S.S.*—See Reports, p. 859.

---

2. *On Depression of Prices and Results of Economy of Production, and on the Prospect of Recovery. By* HYDE CLARKE, *F.S.S.*

The author said that the expectations in 1884 of the sale of the corn crops in the United States and Canada had not been realised, nor were hopes of recovery to be built on the crops of 1885. The sale in the European market of American and other imported corn is limited by the fact that the consumption by human beings (and by animals) is itself limited by what the individual can consume, which is a natural maximum not dependent on price. The amount to be supplied is the deficiency each year on the local crops, which in most European countries meet their own wants, and in the eastern districts allow of export. Corn, too, cannot, like fibres or metals, be stocked for a long time.

Corn, sugar, and coffee are now produced in large quantities, because all the best producing countries are laid open by cheap railways, and the freight to the ocean markets is also reduced.

The effective cause of the great reduction in production and transport is due to the reduction in the cost of steel and iron, consequent on the inventions of Bessemer, Siemens, Thomas, Gilchrist, and others. Whatever the quantity of gold may be, the former price of steel in relation to other commodities will not be regained. As steel or steel iron rails can be made for one-tenth of the cost of thirty years ago, this is an economical fact to be dealt with. Cheap railways and cheap ocean steamers are now making their influence felt.

With regard to gold coinage, the effect of any supposed short supply cannot be measured from one year's supply, or five, or ten years', as the effect has to be calculated on the whole mass of gold coinage existing in the world, whatever that may be. Gold is a metal coined over and over again, sometimes for centuries, and the coinage of a year is in reality in a great degree recoinage. The wear and tear on coinage is much less in the whole world than is usually estimated, as much coin is hoarded, or is subject to sluggish circulation. Manufacturers of gold take new coins and make them into rings, chains, jewellery, and give back supplies of bullion to the mint. The wear and tear of manufactured gold is also limited. Manufactured gold and coinage act and react on each other, but a positive pressure on coinage is supplied from manufactured gold.

It is not possible to ascertain the real and effective total of gold coin in circulation in the world at any moment, and if we could ascertain that, we do not thereby learn the ratio of its efficiency. This is not immediately relevant to its quantity, but to the greater or less rapidity in its circulation or turn-over, dependent on sluggishness or energy of trade, panic, war, famine, hoarding, and many other causes. At present no practical evidence has been adduced that a diminished supply of gold is the cause of lower prices.

With regard to the question of recovery, it will ultimately depend on the readjustment of the new economical conditions. Temporary fluctuations of price may be caused, as was seen this year, by war and rumours of war; also by short crops, or by the discovery of some new mineral commodity. The course of economical events is, however, in the direction of discoveries still further diminishing the amount of labour required for production. The low prices may, however, assist in their own readjustment. At the present moment half the population of the world—in India, China, and Japan, five hundred millions in number—are under the influence of old traditional prices, which in some cases give daily wages of *2d.*

As these rates for wages and commodities are raised to the European standard, and they have been rising of late years, the people will have a larger exchangeable surplus for the purchase of goods, and a diminished power of competitors in production. Indian wheat is raised with wages of $2\frac{1}{2}d.$ per day.

3. *On Customs Tariffs.* *By* A. E. Bateman.

---

4. *How its Fiscal Policy may affect the Prosperity of a Nation.*[1] *By* Alexander Forbes.

The author said that if free trade could be universal, it would be indisputably better for Great Britain and all other nations; but it will never become so, as no two nations are similar, either in their position or products, and each will always naturally follow that fiscal policy which recommends itself most to its own individual interests.

It was advantageous for nations not to have a hard and fast fiscal policy, because without it, they could the better maintain their bargaining powers with other States.

It was this bargaining which England by her pronounced free trade had lost, and the loss of which was the principal if not sole cause of our diminishing and unremunerative export trade, and consequent commercial depression and agricultural distress.

England had only to announce that she would treat every country in future as she was treated by it to have the whole world competing for her trade, and willing to do business on the principle of reciprocity. Since 1846 we had as a nation followed too much the policy of studying the interests of the mere consumer, an extraordinary fallacy for a practical and manufacturing people. If our artisans had to pay *8d.* for the 4lb. loaf, and had a shilling to buy it with, it was surely better than that they should be offered for *6d.* what they were through want of employment without the means of purchasing.

The fiscal policy of a State should be guided by the same principles as controlled a business man in his own relations. The latter preferred to give his orders to such as were customers of his own, even although in some cases he might more advantageously place those orders elsewhere, and so gain an immediate partial benefit, at the cost of a subsequent permanent loss.

If the customs duties imposed by other countries with whom we traded were swept away, the demand for goods of British manufacture would be enormously increased.

If we could not induce foreign countries to trade with us on the principle of reciprocal free trade, let us at least place ourselves on an equality with them, and take advantage of the opportunities of making them share part of our heavy taxation by imposing customs duties on the goods they sent into our markets.

If statesmen would not initiate legislation in this direction for fear of bringing disaster to their party, the day was not far distant when the working men would take the question of our fiscal policy into their own hands.

It was quite evident from our experience of forty years, that through mere example we were powerless to induce other countries to adopt free trade principles as we understand them, and it was equally manifest that if we conceded to foreigners facilities to trade with us which they in turn refused to reciprocate, we must as a manufacturing and commercial nation be serious losers.

For not only did the almost prohibitory tariffs imposed by foreign nations preclude our trafficking profitably with them, but, by our own fiscal policy, our home manufacturers did not enjoy in their own market their legitimate trade, through our encouraging the unfettered and ever-increasing competition of foreign producers, whilst we were at the same time, by not imposing customs duties on

[1] Published *in extenso* by John Avery & Co. (Limited), Aberdeen.

what they sent us, depriving our exchequer of an enormous source of revenue which would tend to greatly lessen our imperial taxation.

The outcome of such a policy as Britain is at present following must ultimately disable her from supporting her present population, without which she cannot long maintain her independence, and with the loss of it, at no distant date, must follow all the privileges and advantages which accompany and flow from nationality and empire.

---

5. *On the Incidence of Imperial Taxation.* *By* Dr. W. A. Hunter.

The object of the paper, the author said, was to determine with as close an approximation to accuracy as our information admitted in what manner the burden of Imperial taxation was borne by the richer and the poorer classes of the community. The gross income for the year ending March 1882—the census year—was, in round numbers, 80 millions, of which 10 millions were receipts not in the nature of taxation. The remaining 70 millions consisted of a sum of $43\frac{1}{3}$ millions raised from tea, coffee, tobacco, and spirits, forming a burden on all classes of the community. It was, of course, true that a poor man who consumed none of these articles almost entirely escaped any share of this burden; but the same remark was equally true if he was a rich man. The balance of $26\frac{2}{3}$ millions was raised by taxes that fell upon a limited class, which was nearly, but not altogether, co-extensive with the class of persons liable to pay income-tax. These taxes comprehended income-tax, house duty, some of the excise licences, railway duties, death duties, stamps, and wines. Some of these taxes fell to a certain extent also upon incomes under 150*l.* a year, so that the sum he had stated at least somewhat exaggerated the amount of the contribution made by the well-to-do classes; but, in order to weight the scales as much in favour of the rich as possible, he credited them with the whole of the taxation. The class represented by the income-tax payers amounted to six millions of people, and the rest of the population to 29 millions. The gross income of the former class he estimated at 650 millions. It must be remembered, however, that in the Inland Revenue returns a great many under estimates occurred which eluded the vigilance of tax-gathers, this being especially the case as regarded foreign securities. But taxation ought not to be based on the gross income. The deduction allowed by the Income Tax Commissioners of 120*l.* a year on incomes under 400*l.* was excessive. Mr. Giffen estimated 12*l.* per head as the reasonable sum that ought to be deducted before one could fairly assess the taxable income. He was not prepared to say that 12*l.* was excessive, but he proposed to put it at the somewhat lower figure of 10*l.* This would give a total of 60 millions to deduct from the 650 millions, or a total taxable income of 590 millions. The total sum paid in taxation by this class, including their share of indirect taxation, was 34 millions, which, on 590 millions, amounted to 5*l.* 15*s.* 3*d.* per cent. It is not easy, Dr. Hunter went on to say, to ascertain the aggregate income of the 29 millions of people whose income does not bring them within Schedule D. Two estimates have been made—one by Mr. Giffen, the other by Professor Leone Levi—of the gross earnings of the working class, a class that corresponds very nearly to the 29 millions. Mr. Levi puts the total at 520 millions; Mr. Giffen at 620 millions—an enormous discrepancy. Mr. Giffen's figures would give an average of 21*l.* 10*s.* per head, or more than 100 guineas for every group of five persons. Such an estimate is hardly consistent with the experience of those who are acquainted with the condition of the working classes. I have endeavoured to test those figures, and have obtained a return of the wages under 150*l.* a year from the Northern Co-operative Company, paid under the following departments:—grocery, bakery, clothiery, butchery, boot and shoe, meal mill, coal, stable, watching and lighting, and counting-houses. The proportion of men employed is somewhat higher than the average; the proportion of women less, and that of boys and girls greater than the average. Although in some occupations men may earn higher wages than those employed at the co-operative stores, yet, having regard to the lower wages paid in rural districts and to the poverty of Ireland, there can be no doubt that the earnings of the employés exceed the average of the whole country.

Correcting the returns so as to make the proportion of men, boys, girls, and women the same as the average proportion throughout the United Kingdom, and adding the due proportion of persons unemployed and maintained by the employés, I find that the average annual earnings per head amount to $19\frac{1}{3}l.$ Upon this basis the gross earnings of the non-income-tax-paying population would amount to 560 millions per annum. There seems no reason to believe that this is too low an estimate. From this sum of 560 millions of gross income we must make a deduction of $10l.$ per head, as we have already done in the case of the income-tax-paying class. This gives us 270 millions of taxable income, of which 36 millions is paid in taxation, a sum equal to $13l.$ $6s.$ $8d.$ per cent. on the income of the poorer class, as compared with $5l.$ $15s.$ $3d.$ per cent. on the income of those who are fortunate enough to require the attention of the Inland Revenue Commissioners. The conclusion, therefore, is that the poorer classes of the population are taxed more than twice as much as the richer class in proportion to their taxable income. Or the result may be stated thus. The poorer class, having regard to their taxable income, ought to contribute about 22 millions a year, whereas they are made to pay 36 millions; and the richer class, who ought to pay 48 millions, escape with a contribution of 34 millions. In order to equalise taxation, it would be necessary to reduce the Customs and Excise to the extent of 15 or 16 millions a year. These figures, however, fail to give an adequate conception of the extent of the burdens actually thrown on the poorer classes. The amount received by the Government from the richer classes is about equal to that which is paid by the latter; but the amount paid by the poorer classes is far in excess of that which is received by the Chancellor of the Exchequer. It is the nature of all taxation of commodities to take more from the taxpayer than is received by the tax-gatherer. Dealers in articles thus taxed require a larger capital for their business, and the cost of the article is enhanced by an inevitable allowance for interest and risk. The Chancellor of the Exchequer receives 36 millions from the poorer classes, but the cost of the articles which they purchase is enhanced by considerably more than 36 millions. This increase cannot be put at less than 25 per cent. The real burden of taxation is thus raised to 45 millions, or nearly 17 per cent. on the taxable income of those who make less than $150l.$ per annum. In the light of these facts the protest that is sometimes raised against graduated taxation appears somewhat out of place. We have graduated taxation, only instead of increasing the burden of taxation in proportion to wealth, we increase it in proportion to poverty. The more able a man is to pay the less is he taxed; the less able he is to pay the more is he taxed.

TUESDAY, SEPTEMBER 15.

The following Papers were read:—

1. *State Guarantee of War Risks. By* JOHN CORRY.

The object of this paper is to advocate the advisability of war risks at sea being guaranteed by the State, instead of as at present being covered by special arrangements with individual underwriters. The author, after referring to the enormous development of our trade, points out how largely we are dependent upon foreign sources both for the supply of our food and raw materials, and how helpless we would be, in the event of war with one or more of the Great Powers, if we were unable to maintain our communications abroad. He refers to instances in which Governments have paid compensation for losses sustained through the operations of war, particularly in the case of the Alabama claims, the bombardment of Alexandria, and the French Indemnity of 1871. A State guarantee against war risks at sea would therefore be merely an extension of a principle which has been already admitted. One of the great dangers to be avoided is the transfer of our tonnage to neutral flags in consequence of the extra premiums necessary to meet war risks.

The author is of opinion that if the volume of our trade were once diverted from its present channels it would be very difficult, if not impossible, to restore it. As a great manufacturing country we are not only dependent upon the economic supply of raw materials, but also upon having sufficient outlets for our finished goods. If the raw materials were not forthcoming the temporary stoppage of our industries would undoubtedly lead to a transference of a large portion of our trade to foreign countries. The author further considers that a State guarantee against war risks would tend to strengthen our relations with our colonies and dependencies, and might lead to a consolidation of the whole empire. In order to safeguard the great interest involved, some improvements would be required in our navy, but the author does not consider that the maintenance of a huge standing army would become a necessity for this country. The cost of war risks must eventually be borne by the nation at large, but if these risks were undertaken by the Government the author maintains that the expense would be vastly less than that which would be incurred through extra premiums and the attendant evils in the event of a great war breaking out.

The objections to the proposal, he maintains, are more apparent than real, and any difficulties could be easily overcome in carrying out the details by principles of procedure which are already well understood. The author claims that this subject is not brought forward in the interest of any particular trade, but upon economic and national grounds. He sums up with the following propositions, which convey a concise statement of his views:—

The whole question can be practically summarised in the following propositions:—

1st. That as the existence of this country absolutely depends on foreign supplies of food and materials anything that would risk the failure or enhance the cost of those supplies must be a national loss.

2nd. That as the trade and carriage is now mainly in British hands it is all important that it should so continue, and not be transferred to, or get into the hands of, our foreign competitors.

3rd. That the international effect of such a declaration as we have advocated would be highly advantageous to our commerce throughout the world, and would prevent neutral nations taking that selfish interest in our position which the hope of future gain might encourage them to show. If any nation expected to gain large material advantages by our being engaged in war we could not as readily look for its sympathy or co-operation.

4th. That if a large amount of our tonnage was transferred to neutral flags, or the neutral flag was largely engaged in our carrying trade, the volume of trade thus once shifted would be very difficult, if not impossible, to restore.

5th. That the cost to the consumers, if Government failed to meet the emergency in case of war, would be enormously enhanced directly and indirectly.

6th. That the effect of such a declaration would tend in the strongest way to bind our colonies and dependencies together, and to unite them to this country.

The products of our colonies and dependencies are now so vast and varied that we could soon be independent of all other sources of supply.

7th. That as the power of machinery has so much reduced the special advantages or facilities which we as a nation have enjoyed over others in the way of manufacturing, any temporary disadvantage to, or disarrangement of, our trade might direct it into other channels, from which it could not afterwards be recovered.

I will only add that the question of indemnity against war risks has not been brought forward here with the idea of benefiting any particular trade, but on account of its direct bearing upon the economic supply of food and rough materials, and the distribution of our manufactures throughout the world.

---

2. *On the British Standard of Value.* *By* Dana Horton.

---

3. *Sliding Scales in the Coal Industry.*[1] *By* Professor J. E. C. Munro.

There are at least eight sliding-scales in use in the coal industry, viz.: the Durham scale of 1884; the Cumberland scale of 1884; the Northumberland scale of 1883; the Monmouthshire and South Wales Association scale of 1882; the Ocean scale of 1882; the Ferndale scale of 1882; the Somersetshire scale of 1876; the Bedworth scale of 1879.

The following scales have now been abandoned: the North Wales scale of 1880; the South Staffordshire scale; the West Yorkshire scale of 1880; the Shropshire scale.

The number of miners in the United Kingdom is about half a million, and of these 123,000 have their wages governed by sliding-scales. A sliding-scale is based on two standards: (1) a standard price of coal, and (2) a standard of wages, the latter being payable when the former is realised. As the price of coal falls above or below the standard price, wages fall or rise above the standard wages. A certain agreed variation must take place in the price of coal (*e.g.* 4*d.*) before any variation occurs in wages; accounts being examined every three or four months in order to ascertain if any variation has occurred during the previous period.

The different standard prices adopted by the existing scales are as follows:—Durham, 3*s.* 10*d.* and under 4*s.*; Cumberland, 4*s.* 6·19*d.* and under 4*s.* 7·69*d.*; Northumberland, 4*s.* 8*d.* and under 4*s.* 10*d.*; Association, 7*s.* 8*d.* and under 8*s.*; Ferndale, 8*s.*: Ocean, 10*s.* and under 10*s.* 4½*d.*; Somerset, 10*s.*; Bedworth, under 5*s.* 6*d.*

The variations in pıices that result in variations in wages are as follows:—

—	For every rise or fall of	Wages are to rise or fall: Hewers, Enginemen, Mechanics, Cokemen, and Banksmen	Wages are to rise or fall: Other Surfacemen
	s. d.	Per cent.	Per cent.
Durham (Standard 3*s.* 10*d.* and under 4*s.*) . .	0 2	1¼	1
Between 5*s.* 10*d.* and 6*s.* 10*d.* . . .	0 2	2½	2
Northumberland (Standard 4*s.* 8*d.* & under 4*s.* 10*d.*)	0 2	1¼	1

[1] Published *in extenso* by John Heywood & Co., London and Manchester.

Bedworth Collieries hewers receive a coal allowance if they are married. In Cumberland no allowances are made.

The hours of labour, or 'shift,' as the working day is technically called, vary under the different scales.

The Somerset, Ocean, and Bedworth scales provide for a minimum wages, and the Somerset scale has also a maximum wages.

The average price of coal is ascertained by accountants pledged to secrecy as to details. In Durham, Cumberland, and Northumberland, the price is the average price at the pit's mouth. In South Wales the price is the price delivered free on board at the port of shipment. This latter price, therefore, evidently includes cost of carriage from the pit to the port—a fact that will explain why the standard price under the South Wales scales is so much higher than the standard prices under the Northern scales. The Somerset scale takes as the price the price delivered at the nearest railway station or wharf.

The advantages of sliding-scales may be reduced to two heads. They give (1) a steadiness to trade, and (2) a steadiness to wages, in so far as disputes between employers and employed tend to render trade and wages unsteady.

The sliding-scale is one more proof that wages are to be regarded as the part of the produce obtained by the labourer, inasmuch as the miner is paid in proportion to the value of the coal raised by him.

Historically, the sliding-scales are connected with supply and demand. The standard wages in most instances are the wages payable at the time the scales were introduced, and the supply of labour as compared with the demand for it was one factor in forming those rates. The scarcity or abundance of labour might lead to a modification of a scale, but this is less likely owing to the spirit of combination that exists in the coal trade.

Legally, the sliding-scale is to be regarded as a part of the contract of service entered into between the mine owner and the miner, prescribing what wages are to be payable during the time such contract continues. Only those persons are bound by a scale who give an express or implied assent to it, and whether such assent has been given in a particular instance would be a question of fact for a jury.

---

4. *Anomalies in the condition of Scotch Miners in contrast with other unskilled Labourers.* *By* William Small.

1. All tools requisite for the prosecution of their labour they are compelled to supply, *i.e.*, picks, hammers, shovels, stemmers, drivers, wedges, &c., to the value of from 30*s*. to 40*s*. Other labourers—ploughmen, quarrymen, gardeners, furnacemen, roadsmen, surfacemen, &c.—have all these supplied from capital as part of working plant. Why should miners be compelled to furnish their appliances from the result of labour? The average income of miners is under that earned by any of the foregoing. As a true economic principle, capital should supply all appliances of labour, whatever conventional authority may say to the contrary.

2. When manual power is deficient in intensity to secure success in mining, artificial force is a necessity. Hence powder, dynamite, lime, &c., are in demand. But why should the wage fund of the labourer be compelled to bear the burden? And here the anomalous condition of miners is again shown in bold relief. Are seamen, if unable with oar and sail to propel a vessel, compelled from their wage fund to supply steam; to shape a heavy bar, is a blacksmith called upon to bear the cost of a steam hammer; a quay labourer a steam crane; a quarryman blasting-powder; or a husbandman, unable to thrash all the season's crop with a flail, a steam thrasher? The miners are now beginning to think that capital should supply artificial where manual power is deficient.

3. The miner is compelled to supply himself with light to pursue his occupation because his factory is situated many fathoms underground; but in no other case (generally known) are workmen compelled to illuminate their workshops. The development of electricity as a mine illuminant may ultimately remedy the anomaly, but from conventional precedent employers may charge their workmen for its use.

The perfection of safety-lamps is yearly increasing the miners' outlay, being more costly at purchase and more difficult and expensive to maintain.

4. Royalties are also a source of annoyance, friction, and injustice to the miner; the theory of royalties is meanwhile out of consideration. The case stands thus. A miner may be digging coal at from $7\frac{1}{2}d.$ to $1s.\ 6d.$ per ton—but, for a case, say $10d.$, and the royalty in that seam $1s.\ 4d.$ for a week. The miner earns $20s.$, with deductions $2s.\ 2d.$; nett earning $17s.\ 10d.$, as against $32s.$ to the landlord for royalty. The case is a strong one, but in Lanarkshire the average royalty is $1s.$ per ton. The miners hold that, as formerly and as is still the law of Scotland, such royalty charges should only be exacted by the realm. The idea of forming a 'National Benevolent and Insurance Fund' from such charges is rapidly gaining ground, following the precedent of France, and developing the Knapp Shaft Verein of Germany.

5. The monetary aspect of the foregoing matters is a very serious consideration to working miners, demanding for tools an outlay of $30s.$ to $40s.$; while for weekly charges for oil, powder, sharpening wedges, shafts, &c., they are never under $2s.$ or $2s.\ 6d.$, and thus with the royalty tax and capital exactions their labour is handicapped and natural expansion hindered.

---

5. *The Statistics and some points in the Economics of the Scottish Fisheries.* *By* William Watt, *F.S.S.*

The author began by stating that the value of the Scottish fisheries may be roughly estimated at $3\frac{1}{2}$ millions sterling per annum, or $1l.$ per each unit of the population, of which two-thirds are derived from herring. The other sea-fishes yield only three-quarters of a million—haddock producing 300,000$l.$, cod and ling 266,000$l.$ (it might easily be a great deal more); while the yield from whitings, flat-fishes, and the rest is comparatively small. Shellfish reckon in the Fishery Board's statistics for 81,000$l.$, and salmon for 275,000$l.$ The greatest by far, as well as most expansive, of Scottish fishery industries is the 'white cured herring' trade, which in magnitude has more than doubled within the last quarter of a century.

In ten years,	1855–64,	there were cured yearly	625,000 barrels;
„	1865–74	„ „ „	775,000 „
„	1875–84	„ „ „	1,100,000 „
But in the five years,	1880–84,	„ „ „	1,367,000 „
	And last year, 1884,	there were cured	1,700,000 „

The fishermen work at a much greater distance from the land than they did a quarter of a century ago; they have better boats, and a great increase of netting. More than one-half of last year's catch of herrings, namely, 856,000 barrels, was landed within a radius of fifty miles of Aberdeen. Aberdeenshire had 750,000 barrels, equal to an item of 89,000 tons in the general food supply, of which the first price was about eight guineas a ton, or one penny a pound. The same county supplies yearly some 45,000 cattle for conversion into beef, yielding about 15,000 tons, or possibly a little more; worth, with the offal, between $1\frac{1}{4}$ and $1\frac{1}{2}$ million sterling. The entire beef-production of Scotland in a year is about 110,000 tons, and its value, at $75l.$ a ton, $8\frac{1}{4}$ millions; add 70,000 tons of mutton, at $6\frac{3}{4}$ millions, and the animal-food produce of our Scottish fields and pastures is 180,000 tons, and its value 15,000,000$l.$ The produce of the sea, exclusive of shell-fish and salmon, is 275,000 tons, and its value about three millions. In other words, Scotland's contribution of fish to the general food supply is one-third more in quantity and four-fifths less in prime cost than its contribution of beef and mutton.

Eleven-twelfths of last year's herring supply were cured for export, and of the actual exports a still higher proportion went to Germany and Russia. A great change has come over the course of the trade within the last fifty years, as is shown by the following table of exports:—

Year	To Ireland	To the Continent	To places out of Europe
	Barrels	Barrels	Barrels
1834	149,000	56,000	67,000
1859	69,000	203,000	748
1884	35,000	1,149,000	960

The abolition of slavery in the West Indies nearly put an end to the exports of Scotch herrings to 'places out of Europe'; and the potato famine in Ireland led to the introduction of Indian corn and a partial change of dietary there, and to a wholesale exodus of the herring-eating population. We have now only two customers of any importance—Germany and Russia; and it would be more satisfactory if we depended less upon one or two foreign markets. The fishermen number just 50,000, and possess a capital, in boats, nets and lines, of 1,750,000*l.* Those of the north-eastern coast especially are an industrious, saving, and comparatively wealthy class. Many of them are owners of the houses in which they live. They have also substantial sums of money lodged with the banks. Having made some inquiry into this matter, he was enabled, through the courtesy of those connected with banking administration, to state that of the deposit receipts outstanding at twelve branches, in as many of the coast towns, 21 per cent., or more than a fifth of the whole number, are held by fishermen. Their accumulation of savings is thus very considerable, and it is being added to year by year. He might say that one of the branches is almost wholly supported by fishermen. Forty years ago the fishermen of Scotland and the Isle of Man numbered 61,000, and their property in boats, nets, and lines was estimated as worth $1\frac{1}{4}$ million, as compared with $1\frac{3}{4}$ million held by 50,000 Scotch fishermen now. The average value for each man and boy employed was then 20*l.*; it is now 35*l.* So far as the fishermen are concerned, the Scotch herring fishery is a co-operative industry in which capitalists and labourers are united in the same persons. The adoption of steam-power for fishing vessels would save much inconvenience and loss, but would render necessary such an increase in the size and cost of the vessels as would probably to a large extent destroy the pleasant co-operative system at present in vogue.

The system of engagements between curers and fishermen with its accompaniment of a large prepayment months before the fishing begins and irrespective of the quantity caught, was described, and its evils were pointed out. "The brand"—a Government certificate of the quantity and quality of the goods contained in a barrel of cured herrings—was also briefly discussed. It is liked in the trade as facilitating transactions, and being optional and supported by fees, it is not oppressive, while the dependence of the industry upon one or two foreign markets renders its suppression inexpedient. The great need is access to more markets.

---

6. *On the Pauperisation of Children by the Operation of the 'Scotch Education Act,* 1872.' *By* MATTHEW BLAIR.

The object of this paper was to set forth some of the evils arising from the operation of the 'Scotch Education Act, 1872,' inasmuch as it compels poor people who have never received 'parochial aid' to pauperise their children.

Section 49 of the Act requires parents who cannot pay for the education of their children to apply to the parochial board, that the fees may be paid out of the poor fund.

Section 70 provides that poor parents who cannot pay their children's fees, and refuse to take poor funds for the purpose, must go to prison for fourteen days.

In the year 1874, the number of the children of non-pauper parents who had their fees paid in part or whole from the poor fund was 2,377, while in 1884 the

number had risen to 15,545, an increase of nearly 700 per cent., the operation of the Act being to undermine the independence of poor Scotchmen.

The remedy suggested is to increase the school rate one-fourth, also to increase the Government grant one-fourth, which would enable Scotch school boards to grant free education up to the fifth standard, at which stage children can leave school.

WEDNESDAY, SEPTEMBER 16.

The following Papers were read:—

1. *Agricultural Investigation and Education.* *By* THOMAS JAMIESON.

Attention was drawn in this paper to the growing tendency to speak of 'Agricultural Science,' a term directly pointing to education in such parts of what is called 'pure science' as can be usefully applied to aid the industry of agriculture. The term 'Agriculture Science' is welcomed as indicating a better realisation of the relation of science to agriculture, but a warning is given against assisting in forming the notion that agriculture is itself a science, and a counsel to keep in view that it is merely an industry intended for money-making, with aims and interests different from those of science, a distinction which in the interest of investigation it is desirable to maintain.

It is also sought in this paper to point out the present defective provision for agricultural education, and that much of the education that is provided is improper in consequence of its consisting of assumed and unproved matter. A practical suggestion is also made bearing both on investigation and education. In regard to agricultural investigation, serious obstacles to its advance are, on the one hand, the unknown or desultory support that is given to it, and on the other hand, the constant reminder that the aim is mercenary, in other words, that those among whom the investigator has to distribute the results of his work have no interest in it beyond its power of seeming to increase pecuniary gain.

The agricultural investigator cannot altogether lose sight of the fact that his researches are carried out with but a sordid money-making object immediately in view; but there is an ultimate object of a higher kind which it is desirable to look to; otherwise evil consequences follow, such as the alienating from the work men who seek knowledge for the sake of knowledge, and who are best fitted for bringing out truths that may aid the industry. It is, therefore, thought important to emphasise and realise this higher aim. To do this one has merely to separate the agriculturist from the ultimate object altogether, and to regard him simply as a means to an end, the end being increased production, more food for all, less need to make life a toil, and hence more leisure to enjoy life. It is perhaps correct to say that, but for the element of discontent, increased production means increased happiness, than which perhaps no higher aim can be held out.

After investigation comes, almost of necessity, education. Agricultural education is properly education in agricultural science; for although some contradiction may seem to be conveyed in adding that agricultural education should consist not only of what is learned in the laboratory or experimental field, but also of facts gained by actual experience or practice on the farm, yet the attendant qualification is important, namely, that neither the one nor the other should be taught from the educational chair till the one has verified the other. On the one hand, the teaching of the laboratory should be confirmed, both on the experimental field and on the farm; on the other hand, the teachings of the farm, should be submitted to the test of the laboratory and experimental field before either should form a part of education. So that, whether the fact has originally been found on the farm or in the laboratory, it would thus pass into the domain of agricultural science, that is to say of proved matter, before it is taught. Agricultural education ought to consist of two parts.

1. The unlearning of what is unsupported by scientific proof, and

2. The learning of what has been fully proved.

In the first branch should be taught the custom to require proof of all that is asserted, and to become acquainted with what constitutes proof. In the second branch the student should go through—

1. The course of the lecture-room, which is best adapted for lucid explanation, but he should be able to go from that place to

2. The Laboratory, in order to confirm what is comprehended, to clear up what he has but hazily understood, and to correct what is erroneous.

3. He should be able to go to an agricultural museum to see the proofs of former trials, illustrations in actual forms, the connection of one part of agriculture to another, and the systems and results of cognate work in other countries.

4. He should have an opportunity of passing to the Experimental Station to realise the application to plants, to see the effect of different seasons, to compare the influence on different plants of the same treatment and the same season, and finally, to learn how to question nature.

It might be added, 'Let him then go to a farm to acquire a knowledge of agricultural practice.' But this is not agricultural education; it is agricultural training, by which he becomes skilled in judging cattle, judging weather, in arranging work, in the drying and storing of crops, &c.; this training is both assisted and forearmed, as it were, by the previous education; by it the student is enabled, that is to say, both to comprehend what practice merely states, without being able to explain, and to perceive errors in practice.

It seems hardly credible that for this, the largest industry of Britain, there are only four places where the desired form of education can be obtained even in a partial way, while none of these places have any State aid. National support is given only in aid of a system of education, which, no doubt, has done much good directly and indirectly, but which partakes of the unproved form of education just alluded to. Now as agricultural investigation should precede education, one might say that the building has been raised by State aid before the foundation has been laid, and, consequently, that the work must become more unstable the longer the system is carried on, and that unless a radical change be made it may be ultimately expected to fall. The work has not yet proceeded so far, perhaps, as to make it yet too late to support it without much interference with the machinery now in action, and perhaps no more useful project could be suggested by which the Secretary of State for Scotland should inaugurate his high post than by being the pioneer in instituting a simple, sensible, well-planned, and not too extensive series of experiments, to be carried out in every county in Scotland under scientific supervision. The results of such a scheme of experiments faithfully recorded, gathered up, and collectively considered by competent persons, would in the course of a few years be, one might say, certainly productive of results of high educational and high national value. Repetitions and extensions of such work would ultimately form the basis of true education that from its very truth would exert its force, and thus might be expected to find its way into the daily practice of agriculture—a circumstance which has not hitherto been attained, probably from the fact that the education has not been based on a proper foundation.

The object of this short paper might be summed up in a few lines. It is intended to draw attention to certain features that probably are tacitly recognised, but are liable to be lost sight of, to the hurt of agriculture, to the hindrance of agricultural investigation, and to loss to the nation.

1. That the aim of agricultural *investigation* is increased knowledge and increased production, and as the latter must benefit the whole nation, this aim should suffice both to ensure national support and to attract and encourage investigators.

2. That the aim of *agriculture* is pecuniary gain to those actually engaged in or having capital engaged in that industry, and that consequently to hinge investigation as a dependent upon it is to expose investigation to a languishing existence or to starvation; for, although the agriculturist, partaking of the rôle of the scientist, may indeed on occasion extend to it sympathy, support, or gratitude, yet it is only when the point has been reached of clearly pointing out a road to gain that as

an agriculturist he can be expected to do his part, namely, of adopting and carrying into practice the results of investigation.

3. That agricultural *education* should be proceeded by and directly based upon agricultural investigation. It should be limited to facts scientifically proved, and should be associated with means of individual verification.

4. That education that does not proceed on this basis, and is not limited to that line, is likely to be pernicious, as likely to perpetuate error.

5. That as Government has undertaken the support of agricultural education, it might be advised to place it on a sure foundation, before it is too late, by instituting a well-considered scheme of agricultural investigation.

---

2. *Policy in Taxation.*[1] *By* J. B. Greig.

The circumstances of the time lend emphasis to the demand for reform. As Britain declines to afford adventitious aid, so it is the more bound to avoid interposing adventitious obstacles to the home merchant and producer. Our boasted moderation and caution are apt to degenerate into a hesitant, inconclusive attitude that secures the evils of both competing principles, but the benefit of neither.

The immense gains from a concentrated population are counteracted by a heavy debt, cumbrous officialism, and an immobility of habit, the antithesis of adaptability to circumstances. Budgets are so presented as not to admit of deliberation. While dense population is dependent on manufacturing industry, and that on a low wages rate, which in turn depends on the cost of subsistence, taxes on common articles of diet are still maintained. Coffee and tea are taxed, the former to one-fourth, the latter to the amount of the import cost.

The mode of taxing real property exempts, in effect rewards, those who waste or imperfectly utilise valuable natural agents committed to their care, and provides an inducement to employ movable capital in competition with rather than in aid of native industries.

Barriers are wantonly interposed to men pursuing with free choice certain bread-winning occupations, without any selection by the State of the fittest.

Again, of an obnoxious class are the stamp duties, which make demands on the busy in time, temper, and money, and yield no commensurate gain to the State. In the United States no cheque, receipt, promissory note, transfer disposition, or other document is subject to a revenue stamp; in Britain 151 acts are so burdened, of which 63 are incident to trade, 31 to men following bread-winning occupations.

I do not object to a tax on the profits of trade, but deem a tax on the *operations* at their inception, before it is known if they will result in profit or in loss, most objectionable. In the rudest times, the seed and the tools of the husbandman were passed, and the increase only tithed. On the operations of trade the cheque and receipt stamps bear, and most heavily, on the small trader. The objections urged against existing taxation may be briefly summarised, some imposts being open to our objection, and some objectionable on various grounds.

a. Where the loss to the taxpayer exceeds the gain to the State. The loss is often in the form of inconvenience, unproductive study, delay, and worry.

b. Where the cost of services or commodities is enhanced with the result of prejudicing the home trade in competition.

c. Where the tendency is to discourage the employment of movable capital in this country and to induce its transference to competing countries.

d. Where qualities useful to the State are discouraged, or those injurious to it fostered.

e. Where it arbitrarily restricts the choice of occupation, or the diffusion of trade facilities.

f. Where it induces the use of worse, instead of better, forms of instrument, or the disuse of proper documents and practices.

[1] Published *in extenso* by W. and W. Lindsay, Aberdeen.

g. Where it hinders the ready transfer of property or rights to those most capable of utilising them.

h. Where it ignores the just relations to the State, and *inter se* of taxable subjects, and levies in flagrant disproportion to the benefits conferred.

i. Where it negatives invention in mercantile and financial documents and hinders adaptation to altered circumstances.

---

3. *A new view of the Consequences of Unpunctuality in Railway Trains. By* CORNELIUS WALFORD, *F.I.A., F.S.S.*

I do not purpose on this occasion to enter upon any general discussion of railway management, further than to say that for a full generation after the introduction of railway travelling, the most perverse ingenuity appears to have been brought to bear in order to prevent the masses of the people from enjoying its advantages. One of the natural consequences of this policy, beyond direct loss of revenue, seems to have been that when the masses began to travel, in many cases the railways were not in a position, as to terminal accommodation, &c., to convey them with punctuality; not in a position, in fact, to perform the conditions of their own time-tables.

By means of railways, merchants, traders, professional men, clerks, and others having their vocations in cities and towns, are enabled to reside in the suburbs; but this very fact presupposes the existence of facilities of transit to and from these surburban homes to their business locations.

It is only when violent outbursts of complaint arise in the public press from time to time, that we obtain an insight into the method in which these supposed conditions are fulfilled, or rather are systematically disregarded.

It was through the medium of recently published communications—and I shall only rely upon those authenticated with name and address—that I gathered the facts upon which I am about to comment. Persons living within a ten-mile radius of the southern half of the metropolis spoke of from ten to twenty-five minutes' delay in performing the journey either way as a chronic state of irregularity.

No doubt the landing of tens of thousands of persons daily between the hours of 8.30 and 10.30 a.m., and conveying these away again between the hours of 4 and 6 p.m., is attended with enormous practical difficulties. But the railway companies undertake to do it, and readily enter into contracts to that end.

On the strength of these assurances people remove their homes into the country, and build or buy houses, or enter into rental engagements extending over terms of years. In doing so under the present state of things, other perils than those involved in such financial engagements await them. These it is the especial object of this paper to comment upon.

I will take for my particular text the case of a systematic delay of fifteen minutes on the journey each way—by no means a maximum instance of delay. *That* involves in the six working days of the week a loss of three hours of direct time, amounting in the year of 50 working weeks to 150 hours; equal to 25 ordinary business days of six hours, *or about equivalent to one-twelfth of the city working year.*

This is as applied to one individual. But take the average number of passengers in each of these city trains at 300—rather below than above the number carried on many lines—and see what the accumulated results in wasted time reaches. Then again, multiply this total by the two or three hundred trains running daily into London alone, and the aggregate waste of time can be readily computed into figures almost astounding.

Now if it were simply a matter of waste of time, that could in some degree be taken into account and allowed for in estimating the advantages of a country as against a town residence; but the greater evils of these constantly-recurring delays show themselves in other forms. There is the mental anxiety of the morning in knowing that the business of the day is being thrown back by

every unnecessary minute's delay of the journey, and a consequent struggle on the part of the principals and staff during the day to overtake the time so lost in the journey. In the afternoon the jaded powers are again placed under irritating influences; the garden exercise before dinner shorn of its proportions or altogether lost, or the evening meal delayed or hurried, with corresponding injury to the system. When I hear of men giving up country residence after a few years' trial, on the plea perhaps that railway travelling daily does not suit them, I wonder how much of the trouble arises from these conditions of unpunctual time-keeping and its concomitant mischiefs.

I have not desired in this short paper in any way to overstate the case as against the railway companies. No good end would be served thereby. The question is one capable of some elucidation by every one concerned. It may be that it will be found by railway companies that the purely surburban traffic does not pay—does not or will not pay for the terminal expenditure necessary to render the stations of our great cities equal to the stress entailed during certain hours of the day. If this be so it had better be known, and the tramways—when the ignorance of vestries and local boards shall be overcome—may be found equal to the emergency.

I commend some of the reflections here offered to the careful consideration of our friends of the medical faculty. For some years I travelled about eighty miles a day up and down to business by trains that were reasonably punctual, and found my health benefited rather than otherwise by the repose of the journey.

---

4. *On the Industrial Remuneration Conference.* *By the* Rev. W. Cunningham, *B.D.*

This Conference was organised under the auspices of the Statistical Society to carry out the wishes of an Edinburgh gentleman, who had devoted 1,000*l.* to the purpose of discussing how far the existing system for the distribution of the products of industry was satisfactory, and how far capable of improvement. Many practical suggestions of importance had been thrown out, but it was hardly worth while to commence a discussion of them in detail. It was more desirable to try and understand how a representative Conference of this kind regarded the studies to which Section F was devoted. While there was a very general wish that the Government should collect and publish statistics of wages and prices, this was sought for purely practical purposes, and was no evidence of interest in statistical science. This was further illustrated by the attitude assumed towards statistical inquiries about the progress of the working classes. There was evidently a strong feeling among artisans that the recent inquiries were inaccurate, as no sufficient account was taken of the intensity of labour, or of the irregularity of employment. Besides being inaccurate, the inquiries seemed to many to be irrelevant; they dealt with the individual as isolated, while many wanted to estimate the improvement in the lot of the labourer relatively to the progress of society, and held that when the question was put in this form, there had been no progress among the working classes, and that the attempts to measure it were worse than useless. The discussions at the Conference also showed that economic science was little appreciated, and much remained to be done before the public could be convinced that there is such a science, or cultivated men could be found to agree as to its nature. The Conference also proved that the land agitation had a wider hold than might have been expected, and gave indications of a similar agitation in the immediate future against credit and banking which might be very much more difficult to oppose.

SECTION G.—MECHANICAL SCIENCE.

PRESIDENT OF THE SECTION—B. BAKER, M.Inst.C.E.

THURSDAY, SEPTEMBER 10.

The PRESIDENT delivered the following Address:—

GENTLEMEN,—Two hundred and fifty-seven Presidential Addresses of one kind and another have been delivered at meetings of the British Association since the members last mustered at Aberdeen. I need hardly say that the candid friend who informed me of this interesting fact most effectually dispelled any illusion I may have previously entertained as to the possibility of preparing an address of sufficient novelty and suggestiveness to be worthy of your attention, and I can only hope that any shortcomings will be dealt with leniently by you. One compensating advantage obviously belongs to my late appearance in the field—I have two hundred and fifty-seven models of style upon which to frame my address. My distinguished predecessor, Sir Frederick Bramwell, has a style of his own, in which wit and wisdom are combined in palatable proportions; but were I to attempt this style I should doubtless incur the rebuke which a dramatic critic of Charles the Second's time administered to a too ambitious imitator of a popular favourite: 'He's got his fiddle, but not his hands to play on't.' I must search further back than last year, therefore, for a model of style, and the search reminds me that I labour under a double disadvantage: firstly, that only two addresses intervene between the present one and that of my partner, Mr. John Fowler, with whom I have so long had the honour of being associated, and whose professional experiences, as set forth in his address, are necessarily so largely identical with my own; and, secondly, that within the same period I have read before this Section two somewhat lengthy papers on the work which is at present chiefly engaging the attention of Mr. Fowler and myself—the great Forth bridge.

Although, for the reasons aforesaid, I am conscious that my address may fail in novelty, I cannot honestly profess to feel a difficulty in preparing an address of some kind, for the subjects embraced under the head of 'Mechanical Science' are so inexhaustible that even the youngest student might safely accept the responsibility of speaking for an hour on some of them. Professor Rankine, addressing you thirty years ago, said it was well understood that questions of pure or abstract mechanics form no part of the subjects dealt with in this Section. With characteristic clearness of conception and precision of language, he told you what the term 'Mechanical Science' meant, and, after thirty years' interval, his words may be recalled with advantage to everyone proposing to prepare an address or report for this Section. 'Mechanical Science,' said Professor Rankine, 'enables its possessor to plan a structure or machine for a given purpose without the necessity of copying some existent example; to compute the theoretical limit of the strength and stability of a structure or the efficiency of a machine of a particular kind; to ascertain how far an actual structure or machine fails to attain that limit, and to discover the cause and the remedy of such shortcoming; to determine to what extent, in laying down principles for practical use, it is advantageous for the sake of simplicity to deviate from the exactness required by pure science; and to judge

how far an existing practical rule is founded on reason, how far on custom, and how far on error.' There is thus an ample text for many discourses; but, as I am not writing a treatise on engineering, but merely delivering a brief address, I will confine my attention at present to a particular case of the branch of mechanical science referred to in the last clause of Professor Rankine's definition, and will ask you to consider how far the existing practical rules respecting the strength of metallic bridges are 'founded on reason, how far on custom, and how far on error.'

The first question obviously is, What are the rules adopted by engineers and Government departments at the present time?—and it is one not easily answered. I have for some time past been receiving communications from leading Continental and American engineers, asking me what is my practice as regards the admissible intensity of stress on iron and steel bridges, and in replying I have invited similar communications from themselves. As a result, I am able to say that at the present time absolute chaos prevails. The old foundations are shaken, and engineers have not come to any agreement respecting the rebuilding of the structure. The variance in the strength of existing bridges is such as to be apparent to the educated eye without any calculation. If the wheels of a miniature brougham were fitted to a heavy cart, the incident would excite the derision even of our street boys, and yet equal want of reason and method is to be found in hundreds of bridges in all countries. It is an open secret that nearly all the large railway companies are strengthening their bridges, and necessarily so, for I could cite cases where the working stress on the iron has exceeded by 250 per cent. that considered admissible by leading American and German bridge builders in similar structures.

In the case of old bridges the variance in strength is often partly due to errors in hypothesis and miscalculation of stresses. In the present day engineers of all countries are in accord as to the principles of estimating the magnitude of the stresses on the different members of a structure, but not so in proportioning the members to resist those stresses. The practical result is that a bridge which would be passed by the English Board of Trade would require to be strengthened 5 per cent. in some parts and 60 per cent. in others before it would be accepted by the German Government or by any of the leading railway companies in America. This undesirable state of affairs arises from the fact that in our own and some other countries many engineers still persistently ignore the fact that a bar of iron may be broken in two ways—namely, by the single application of a heavy stress or by the repeated application of a comparatively light stress. An athlete's muscles have often been likened to a bar of iron, but, if 'fatigue' be in question, the simile is very wide of the truth. Intermittent action—the alternative pull and thrust of the rower, or of the labourer turning a winch—is what the muscle likes and the bar of iron abhors. Troopers dismount to rest their horses, but to relieve a bar of iron temporarily of load only serves to fatigue it. Half a century ago Braithwaite correctly attributed the failure of some girders, carrying a large brewery vat, to the vessel being sometimes full and sometimes empty, the repeated deflection, although imperceptibly slow and wholly free from vibration, deteriorating the metal, until, in the course of years, the girders broke. These girders were of cast iron; but it was equally well known that wrought iron was similarly affected, for in 1842 Nasmyth called the attention of this Section to the fact that the 'alternate strain' in axles rendered them weak and brittle, and suggested annealing as a remedy, he having found that an axle which would snap with one blow when worn would bear eighteen blows when new or after being annealed.

So important a matter as the action of intermittent stresses could not escape the attention of the Royal Commissioners appointed in 1849 to consider the application of iron to railway structures, and some significant and sufficiently conclusive experiments were made by Captain Douglas Galton and others. Cast-iron bars 3 inches square and 13 feet 6 inches span between the supports were deflected, both by the slow action of a cam and the percussive action of a swinging pendulum weight. When the deflection was that due to one-third of the breaking weight, about 50,000 successive bendings by the cam broke one of the bars, and about 1,000 blows from the pendulum another. When the deflection was increased from one-third to one-half, about 500 applications of the cam, and 100 blows,

sufficed to rupture two of the specimens. Slow-moving weights on bars and on a small wrought-iron box girder gave analogous results; and the deduction drawn by the experimenters at the time was that 'iron bars scarcely bear the reiterated application of one-third the breaking weight without injury, hence the prudence of always making beams capable of bearing six times the greatest weight that could be laid upon them.'

Although these experiments were entirely confirmatory of all previous experience, they would appear to have little influenced the practice of engineers, since Fairbairn, more than ten years later, in a communication to this Section, said that opinions were still much divided upon the question whether the continuous change of load which many wrought-iron structures undergo has any permanent effect upon their ultimate powers of resistance. To assist in settling the question he communicated to the Association the results of some experiments carried out by himself and Professor Unwin on a little riveted girder 20 feet span and 16 inches deep. Once more the same important but disregarded facts were enforced on the attention of engineers. About 5,000 applications of a load equal to four-tenths of the calculated breaking load fractured the beam with the small ultimate deflection of three-eighths of an inch, and subsequently, when repaired, the beam broke with one-third of the load and a deflection of but a quarter of an inch, which sufficiently indicated how small a margin the factor of safety of four, then currently adopted, allowed for defective manufacture, inferior material, and errors in calculation. Still nothing was done, and the general practice of engineers and the Board of Trade regulations continued unaltered.

Soon after the introduction of wrought-iron bridges on railways, the testimony of practical working was added to that of experiments. In 1848 several girder bridges of unduly light proportions were erected in America, and one of 66 feet span broke down under the action of the rolling load in the same manner as Fairbairn's little experimental girder. Again, in early American timber bridges the vertical tie-rods were often subject to stresses oscillating between one ton and ten tons per square inch and upwards. Many of these broke, as did also the suspension bolts in platforms subjected to similar stresses. In my own experience, dozens of broken flange-plates and angle-bars, and hundreds of sheared rivets, have been the silent witnesses of the destructive action of a live load. Like evidence was afforded by early-constructed iron ships deficient in girder strength. Under the alternating stresses due to the action of the waves weaknesses not at first apparent would, in the course of time, be developed, and additional strength, in the way of stringers and otherwise, become imperative.

If none of the preceding evidence had been forthcoming, the results of the historical series of experiments carried out by Wöhler for the Prussian Ministry of Commerce would alone be conclusive. For the first time a truly scientific method of investigation was followed, and an attempt was made to determine the laws governing the already proved destructive action of intermittent stresses. In previous experiments the bar or girder was alternately fully loaded and wholly relieved of load. Wöhler was not satisfied with this, but tested also the result of a partial relief of load. The striking fact was soon evidenced, on testing specimens under varying tensions, that the amount of the variation was as necessary to be considered as that of the maximum stress. Thus, an iron bar having a tensile strength of 24 tons per square inch broke with about 100,000 applications of a stress varying from *nil* to 21 tons, but resisted 4,000,000 applications of the 21 tons when the minimum stress was varied from *nil* to $11\frac{1}{2}$ tons. The alternations of stress in the case of some test pieces numbered no less than 132,000,000; and too much credit cannot be bestowed by engineers upon Wöhler for the ingenuity and patience which characterised his researches. As a result, it is proved beyond all further question that any bar or beam of cast iron, wrought iron, or steel may be fractured by the continued repetition of comparatively small stresses, and that, as the differences of stress increase, the maximum stress capable of being sustained diminishes.

Various formulæ based upon the preceding experiments have been proposed for the determination of the proper sectional area of the members of metallic structures. These formulæ differ in some essential respects, and doubtless many experiments

are still required before any universally accepted rules can be laid down. Probably at the present time the engineers who have given the most attention to the subject are fairly in accord in holding that the admissible stress per square inch in a wrought-iron girder subject to a steady dead load would be one and a half times as great as that in a girder subject to a wholly live load, and three times that allowable in members subject to alternate tensile and compressive stresses of equal intensity, such as the piston-rod of a steam-engine or the central web bracing of a lattice girder. If the alternations of stress to be guarded against are not assumably infinite in number, but only occasional—as in wind bracing for hurricane pressures, or in a vessel amongst exceptionally high waves—then the aforesaid ratio of 3, 2, and 1 would not apply, but would more nearly approach the ratios 6, 5, and 4.

Hundreds of existing railway bridges, which carry twenty trains a day with perfect safety, would break down quickly under twenty trains per hour. This fact was forced on my attention nearly twenty years ago by the fracture of a number of iron girders of ordinary strength under a five-minute train service. Similarly, when in New York last year I noticed, in the case of some hundreds of girders on the 'Elevated Railway,' that the alternate thrust and pull on the central diagonals from trains passing every two or three minutes had developed weaknesses which necessitated the bars being replaced by stronger ones after a very short service. Somewhat the same thing had to be done recently in this country with a bridge over the Trent, but the train service being small the life of the bars was measured by years instead of months. If ships were always amongst great waves the number going to the bottom would be largely increased, for, according to Mr. John, late of Lloyd's, 'many large merchant steamers afloat are so deficient in longitudinal strength that they are liable under certain conditions of sea to be strained in the upper works to a tension of from 8 to 9 tons per square inch, and to a compression of from 6 to 7 tons'—stresses which the experiments already referred to prove would cause failure after a definite number of repetitions. Similarly, on taking ground or being dry-docked with a heavy cargo on board, it has been shown that vessels are liable to stresses of over 11 tons per square inch on the reverse frames, but no permanent injury results from such high stresses, because the number of repetitions is necessarily very limited.

It appears natural enough to everyone that a piece even of the toughest wire should be quickly broken if bent backward and forward to a sharp angle; but, perhaps, only to locomotive and marine engineers does it appear equally natural that the same result would follow in time if the bending were so small as to be quite imperceptible to the eye. A locomotive crank axle bends but $\frac{1}{34}$ in., and a straight driving axle the still smaller amount of $\frac{1}{64}$ in., under the heaviest bending stresses to which they are subject, and yet their life is limited. During the year 1883 one iron axle in fifty broke in running, and one in fifteen was renewed in consequence of defects. Taking iron and steel axles together, the number then in use on the railways of the United Kingdom was 14,848, and of these, 911 required renewal during the year. Similarly, during the past three years no less than 228 ocean steamers were disabled by broken shafts, the average safe life of which is said to be about three or four years. In other words, experience has proved that a very moderate stress alternating from tension to compression, if repeated about one hundred million times, will cause fracture as surely as a sharp bending to an angle repeated perhaps only ten times.

I have myself made many experiments with a view to elucidate the laws affecting the strength of iron- and steel-work subject to frequent alternations of stress. Perhaps the most suggestive series was one in which I subjected flat steel bars about three feet long, in pairs, to repeated bendings until one bar broke, and then testing the surviving bar under direct tensile and compression stresses to ascertain to what extent the metal had deteriorated. It had come under my notice, as a practical engineer, that if the compression members of a structure were unduly weak the fact became quickly evident, perhaps under the test load; but if, on the other hand, the tension members were weak, no evidence might appear of the fact until frequent repetition of stresses during several years had caused them

to fracture without any measurable elongation of the metal. In the case of crank-shafts, also, the fracture is invariably due to a tearing and not a crushing action. It appeared to me, therefore, eminently probably that repetition of stresses might be far more prejudicial to tension than to compression members, and, if so, the fact ought to be taken account of in proportioning a structure.

This proved to be the case in my experiments. For example, the companion bars to those which had broken with 18,000 reversals of a stress less than half the original breaking weight behaved, when tested as columns thirty diameters in length, precisely the same as similar bars which had done no work at all, whereas when tested in tension the elongation was reduced from the original 25 per cent. to 2·5 per cent., and the fracture appeared to indicate that the bars had been made of three different kinds of steel imperfectly welded together. With a stress reduced by one-fourth the number of bendings required to break the bars was increased to 1,200,000. In this instance the calculated maximum working stress on the extreme fibres was 43 per cent. of the direct ultimate tensile resistance of the steel, and about 30 per cent. of the stress the bar was capable of sustaining as a beam under the single application of a load. Of course, the bars failed by tension, and the extreme fibres had thus deteriorated as regards tensile stresses to the extent indicated by the above percentages. Tested as a column, however, the injury the bar had received from the 1,200,000 bendings was inappreciable. The ductility was of course very largely reduced, but ductility is a quality of comparatively little importance when a material is in compression. There is no ductility in the slender Gothic stone columns of our cathedrals, which, though heavily stressed, have carried their loads for centuries. As I found repeated bendings raised the limit of elasticity, I rather anticipated finding an increased resistance from this cause in long columns. This did not prove to be the case, nor did I find any difference in short columns four diameters in length.

In addition to the preceding experiments with rectangular bars, I have tested the endurance of many revolving shafts of cast iron, wrought iron, and steel, with similar results. About 5,000 reversals of a stress equal to one-half the static breaking weight sufficed generally to cause the snapping of a shaft of any of the above materials. When the stress was reduced and the number of applications increased, I found the relative endurance of solid beams to be more nearly proportional to the tensile strength of the metal than to the breaking weight of the beam, a distinction of great importance where axles, springs, and similar things are concerned. Many of my experiments were singularly suggestive. Thus, it was instructive to see a bar of cast iron loaded with a weight which, according to Fairbairn's experiments, it should have carried for a long series of years, broken in two minutes when set gently rotating. Also to find a bar of the finest mild steel so changed in constitution by some months of rotation as to offer no advantages either in strength or toughness over a new cast-iron bar of the same section.

Although, as already stated, many more experiments are required before universally acceptable rules can be laid down, I have thoroughly convinced myself that, where stresses of varying intensity occur, tension and compression members should be treated on an entirely different basis. If, in the case of a tension member, the sectional area be increased 50 per cent. because the stress, instead of being constant, ranges from *nil* to the maximum, then I think 20 per cent. increase would be a liberal allowance in the case of a compression member. I have also satisfied myself that if a metallic railway bridge is to be built at a minimum first cost, and be free from all future charges for structural maintenance, it is essential to vary the working stress upon the metal within very wide limits, regard being had not merely to the effect of intermittent stresses, but also to the relative limits of elasticity in tension and compression members even under a steady load.

Why an originally strong and ductile metal should become weak and brittle under the frequent repetition of a moderate stress has not yet been explained. Lord Bacon touched upon the subject two or three centuries ago, but you may consider his explanation not wholly satisfactory. He said, 'Of bodies, some are fragile, and some are tough and not fragile. Of fragility, the cause is an impotency to be extended, and the cause of this inaptness is the small quantity of spirits.' I

am sorry to have no better explanation to offer, but whatever may be the immediate cause of fragility, no doubt exists that it is induced in metals by frequent bendings, such as a railway bridge undergoes. This fact, however, is not recognised in our Board of Trade regulations, which remain as they were in the dark ages, as do those of the Ministry of Public Works of France and other countries. With us it is simply provided that the stress on an iron bridge must not exceed 5 tons per square inch on the effective section of the metal. In France it is still worse, as the limiting stress of rather under 4 tons per square inch is estimated upon the gross section, regardless of the extent to which the plates may be perforated by rivet holes. In neither case is any regard had in the rules to intermittent stresses or the flexure of compression members. In Austria the regulations make a small provision for these elements; and American specifications make a large one, the limiting stresses, instead of being constant at 5 tons, as with us, ranging from about $2\frac{1}{2}$ tons to $6\frac{3}{4}$ tons per square inch, according to circumstances. It is hardly necessary that I should say more to justify my statement that, as regards the admissible intensity of stress on metallic bridges, absolute chaos prevails.

Engineers must remember that if satisfactory rules are to be framed, they, and not Governmental departments, must take the initiative. In former days the British Association did much to direct the attention of engineers to this important matter, but, so far as I know, the subject has been dropped for the past twenty years, and I have ventured, therefore, to bring it before you again in some detail. We are here avowedly for the advancement of science, and I have not been deterred by the dryness of the subject from soliciting your attention to a branch of science which is sadly in need of advancement.

Had I been addressing a less scientific audience, I might have been tempted rather to boast of the achievements of engineers than to point out their shortcomings. The progress in many branches of mechanical science during the past fifty years has exceeded the anticipation of the most far-seeing. Fifty years ago the chairman of the Stockton and Darlington Railway, when asked by a Parliamentary committee if he thought any further improvements would be possible on railways, replied that he understood in future all new railways would have a high earthwork bank on each side to prevent engines toppling over the embankments and to arrest hot ashes, which continually set fire to neighbouring stacks, but in other respects he appeared to think perfection was attained. Shortly before the introduction of locomotives it was also thought perfection was attained when low trucks were attached to the trains to carry the horses over the portions of the line where descending grades prevailed, and all the newspapers announced, with a great flourish of trumpets, that a year's experience showed the saving in horseflesh to be fully 33 per cent.

Although these views seem childlike enough from our present standpoint, I have no doubt that as able and enterprising engineers existed prior to the age of steam and steel as exist now, and their work was as beneficial to mankind, though different in direction. In the important matter of water supply to towns, indeed, I doubt whether, having reference to facility of execution, even greater works were not done 2,000 years ago than now. Herodotus speaks of a tunnel 8 ft. square, and nearly a mile long, driven through a mountain in order to supply the city of Samos with water; and his statement, though long doubted, was verified in 1882 through the abbot of a neighbouring cloister accidentally unearthing some stone slabs. The German Archæological Society sent out Ernst Fabricius to make a complete survey of the work and the record reads like that of a modern engineering undertaking. Thus, from a covered reservoir in the hills proceeded an arched conduit about 1,000 yards long, partly driven as a tunnel and partly executed on the 'cut and cover' system adopted on the London underground railway. The tunnel proper, more than 1,100 yards in length, was hewn by hammer and chisel through the solid limestone rock. It was driven from the two ends like the great Alpine tunnels, without intermediate shafts, and the engineers of 2,400 years ago might well be congratulated for getting only some dozen feet out of level and little more out of line. From the lower end of the tunnel branches were constructed to supply the city mains and fountains, and the explorers found ventilating shafts and

side entrances, earthenware socket pipes with cement joints, and other interesting details connected with the water supply of towns.

In the matter of masonry bridges, also, as great works were undertaken some centuries ago as in recent times. Sir John Rennie stated, in his presidential address at the Institution of Civil Engineers, that the bridge across the Dee at Chester was the 'largest stone arch on record.' That is not so. The Dee bridge consists of a single segmental arch 200 ft. span and 42 ft. rise; but across the Adda, in Northern Italy, was built, in the year 1377—more than 500 years ago—a similar segmental arch bridge of no less than 237 ft. span and 68 ft. rise. Ferrario not long since published an account of this, for the period, colossal work, from which it would appear that its life was but 39 years, the bridge having been destroyed for military reasons on December 21, 1416. I believe our American cousins claim to have built the biggest existing stone arch bridge in the world, that across the Cabin Johns Creek, but the span, after all, is only 215 ft., or ten per cent. smaller than the 500-year-old bridge. In timber bridges, doubtless, the Americans will ever head the list, for the bridge of 340 ft. span built across the Schuylkill three-quarters of a century ago will probably never be surpassed. Our ancestors were splendid workers in stone and timber, and, if they had been in possession of an unlimited supply of iron and steel, I fear there would have been little left for modern bridge builders to originate.

The labours of the present generation of engineers are lightened beyond all estimate by labour-saving appliances. To prove how much the world is indebted to students of this branch of mechanical science, and how rapid is the development of a really good mechanical notion, it is only necessary to refer to the numerous hydraulic appliances of the kind first introduced forty years ago by a distinguished past-President, Sir W. G. Armstrong. Addressing you in 1854, Sir William Armstrong explained that the object he had in view from the first was 'to provide, in substitution of manual labour, a method of working a multiplicity of machines, intermittent in their action and extending over a large area, by means of transmitted power, produced by a steam-engine and accumulated at one central point.' The number of cases in which this method of working is a desideratum, or even indispensable, would appear to be limitless. I should be sorry indeed to have anything to do with building the Forth bridge if hydraulic appliances were not at hand to do a giant's work. Let me shortly describe to you what we are doing there at the present time. More than 42,000 tons of steel plates and bars have to be bent, planed, drilled, and riveted together before or after erection, and hydraulic appliances are used throughout. The plates are handled in the shops by numerous little hydraulic cranes of special design, without any complication of multiplying sheaves, the whole arm being raised with the load by a 4-in. direct-acting ram of 6 ft. stroke. A total length of no less than 60 miles of steel plates, ranging in thickness from $1\frac{1}{4}$ in. to $\frac{5}{8}$ in., have to be bent to radii of from 6 ft. to 9 in., which is done in heavy cast-iron dies squeezed together by four rams of 24 in. in diameter, and the same stroke. With the ordinary working pressure of 1,000 lbs. per square inch, the power of the press is thus about 1,750 tons. Some 3,000 pieces, shaped like the lid of a box, 15 in. by 12 in. wide, with a 3-in. deep rim all round, were required to be made of $\frac{1}{2}$-in. steel plate, and this was easily effected in two heats by a couple of strokes of a 14-in. ram. In numberless other instances steady hydraulic pressure has been substituted by Mr. Arrol, our able contractor, for the usual cutting and welding under the blacksmith's hammer.

Hydraulic appliances are also an indispensable part of the scheme for erecting the great 1,700 ft. spans. Massive girders will be put together at a low level, and be hoisted as high as the top of St. Paul's Cathedral by hydraulic power. Continuous girders, nearly a third of a mile in length, will be similarly raised. Not only the girders, but workmen, their sheds, cranes, and appliances, will be carried up steadily and imperceptibly as the work of erection proceeds, on platforms weighing in some instances more than 1,000 tons. It is hardly necessary to say that every rivet in the bridge will be closed up by hydraulic power, the machines being in many instances of novel design, specially adapted to the work. Thus the bed-plates, which in ordinary bridges are simple castings, in the Forth

bridge are necessarily built up of numerous steel plates, the size of each bed-plate being 37 ft. long by 17 ft. 6 in. wide. To grip together the 47 separate plates into a solid mass 3,800 rivets 1¼ in. in diameter with countersunk heads on both sides are required, and, remembering that the least dimension of the bed-plate is 17 ft. 6 in., it will be seen the ordinary 'gap'-riveter would not be applicable. A special machine was therefore designed by Mr. Arrol, consisting of a pair of girders and a pair of rams, between which the bed-plate to be riveted together lies. A double ram machine had for like reasons to be devised for riveting up the great tubular struts of the bridge.

Not merely in the superstructure, but in the construction of the foundations, were hydraulic appliances of a novel character indispensable at the Forth bridge. Huge wrought-iron caissons or cylinders, 70 ft. diameter and 72 ft. high, were taken up and set down as readily as a man would handle a bucket. In sinking these caissons through the mud and clay of the Forth compressed air was used. When the boulder clay was reached the labour of excavating the extremely hard and tenacious material in the compressed air-chamber proved too exhausting, pickaxes were of little avail, and the Italian labourers who were chiefly employed lost heart over the job altogether. But a giant power was at hand, and only required tools fit for the work. Spades with hydraulic rams in the hollow handles were made, and, with the roof of the compressed air-chamber to thrust against, the workmen had merely to hold the handle vertically, turn a little tap, and down went the spade with a force of three tons into the hitherto impracticable clay as sweetly as a knife into butter. Probably, when addressing you thirty years ago, Sir William Armstrong never anticipated that a number of hydraulic spades would be digging away in an electrically lighted chamber or diving bell, 70 ft. diameter and 7 ft. high, 90 ft. below the waves of the sea; but still the spades come strictly within the definition of the class of machines, intermittent in their action and extending over a large area, which it was his aim to introduce. It would be possible, indeed, with the appliances at the Forth bridge, to arrange that the simple opening of a valve should start digging at the bottom of the sea, riveting at a height of nearly 400 ft. above the sea, and all the multifarious operations of bending, forging, and hoisting, extending over a site a mile and a half in length.

It would not only be impossible to build a Forth bridge, but it would be equally impossible to fight a modern ironclad without the aid of hydraulic appliances. Most of the Presidents of this Section have referred in the course of their addresses to our Navy, and certainly the subject is a tempting one, for the progress of mechanical science in recent years could not be better illustrated than by a description of the innumerable appliances which go to the making and working of a modern ironclad. Let me quote a single passage from a pamphlet by a naval officer, which caused a great stir a few years before the Crimean war, that I may recall to your minds what was the speed and what the armament of our fleet at that comparatively recent period. 'Conceive,' said Captain Plunkett, R.N., 'a British and French fleet issuing simultaneously from Spithead and Cherbourg; seven hours' steaming at the rate of six miles an hour will bring them together. A single glance at the heavy and well-appointed tiers of a line-of-battle ship's guns will satisfy anyone that they are no toys to be placed in the hands of novices. Formidable batteries of the heaviest ordnance are there—not a gun under a 32-pounder, and many 68-pounder shell guns.' In little more than a quarter of a century engineers have changed all that, and advanced to 20-knot vessels and 120-ton guns. Archæologists tell us that our predecessors in mechanical science, of the Stone Age, were apparently a thousand or more years in finding out that the best way of fitting an axe was to slip the handle through the axe and not the axe through the handle. Engineers of the present day may be excused, therefore, for occasionally illustrating the rapidity of the advance of their science by contrasting the ships of thirty years ago with our modern ironclads.

The latest type of battle-ship weighs, fully equipped, about 10,000 tons. There are about 3,400 tons of steel in her hull, apart from armour, which with its backing will weigh a further 2,800 tons. The machinery, largely of steel, is about 1,400 tons; the armament, including ammunition, 1,100 tons; the coals, 1,100 tons; and

general equipment, 270 tons. A detailed description bristles with the word 'steel,' and enthusiastic newspaper reporters sent down to Chatham Dockyard can no more 'spin out their copy' with Cowper's oft-quoted lines on the 'Launch of a First-Rate:'—

'Giant oaks of bold expansion
O'er seven hundred acres fell,
All to build thy noble mansion,
Where our hearts of oak do dwell.'

A latter-day poet might boast of 700 acres being exhausted by a single vessel, but it would be a coal-field and not a forest. Accepting Professor Phillips's estimate of the average rate of formation of coal, it may be shown that a hard-worked American liner during her lifetime burns as much coal as would be produced on the area of 700 acres in a period of 2,000 years. We are thus with our steel ships using up our primeval forests at a far more extravagant rate than that at which our immediate forefathers cleared the oak forests. Coal is the great stimulant of the modern engineer. Pope Pius the Second has left on record an expression of the astonishment he felt when visiting Scotland, in the fifteenth century, on seeing poor people in rags begging at church doors, and receiving for alms pieces of black stone, with which they went away contented. To such early familiarity with coal may, however, be due the fact that Scotland has ever led the way in the development of the steam-engine, and that at the date of the battle of Waterloo she had built and registered seven steam vessels, whilst England could boast of none.

Probably none but a poet or a painter would wish for a return to our old oak sailing ships. Some few people still entertain the illusion that the picturesque old tubs were better sea boats than our razor-ended steamers; but, speaking of them in 1846, Admiral Napier said, 'The ships look very charmingly in harbour, but to judge of them properly you should see them in a gale of wind, when it would be found they would roll 45° leeward and 43° windward.' Even our first ironclads were not so bad as that, for although, according to the *Times*, when the squadron was on trial in the Bay of Biscay, the ships rocked wildly to the rising swell and the sea broke in great hills of surf, yet the maximum roll signalled by the worst roller of the lot—the 'Lord Warden'—was but 35° leeward and 27° windward—a total range of 62°, as compared with 88° in the old line-of-battle ships.

We have heard much about the state of the Navy during the past twelve months. A dip into the publications of the British Association—which in this, as in other respects, afford a fair indication of what is uppermost in people's minds—will show that similar discussions have recurred periodically, at any rate, since 1830. If we consult Hansard, as I had occasion to do recently, we find the same remark applies to periods long antecedent to 1830.

It amounts almost to a religious conviction in the mind of a Briton that Providence will not be on his side unless his fleet is at least equal to that of France and Russia united. What would be said now of a minister who met an attack on the administration of the Navy by demonstrating that we had *half* as many line-of-battle ships as Russia; and yet that was literally done less than 50 years ago. Speaking in the House of Commons, on March 4, 1839, the Secretary of the Admiralty said: 'For the last six months unceasing attacks have been made upon our naval administration, describing our Navy as in a state of the utmost decrepitude, and Tory papers say that shameful reductions have been made in the Navy by the present Government. It will be a consolation to my honourable friends to be assured that we have for years lived unharmed through dangers as great as that to which we are now exposed. In 1817 we had 15 sail of the line in commission, and Russia had 30; in 1823 we had 12, and Russia 37; in 1832 we had 11, and Russia 36; and now we have 20, and the Russians 43, having raised our ships to nearly half the number of those of Russia.'

Now as to our guns. The past twelve months is by no means the first occasion on which the armament of our Navy has been attacked. Three years subsequent to the speech of the Secretary of the Admiralty just referred to, Sir Charles Napier made a statement from his place in Parliament of so extraordinary a character that

I make no apology for quoting his exact words, as a reminder of the past and a warning for the future: 'At the end of the last war the guns were in such a bad state that, when fired, they would scarcely hit an enemy, and during the latter period of the American war a secret order was issued that British ships of war should not engage American frigates, because the former were in such an inefficient state.' As for himself, said the plain-spoken old admiral, when he got the order he put it in 'the only place fit to receive it, the quarter-gallery.'

Happily, from our insular position, the change which the progress of mechanical science has wrought in military operations has not been brought home to the people of this country in the same vivid manner that it has to the people of the continents of Europe and America. In the American war, the Franco-German war, and the Russo-Turkish war the construction and equipment of railway works by engineers was an essential part of all great movements. The Russians, in 1877, constructed a railway from Bender to Galatz, 189 miles in length, in 58 working days, or at the rate of more than three miles per day. Altogether, in the three latter months of that year they laid out and built about 240 miles of railway, and purchased and stocked the line with 110 locomotives and 2,200 wagons. They also built numerous trestle bridges, together with an opening bridge and a ferry across the Danube.

We have had recent experiences of the slowness of primitive modes of transport in the tedious advance of Lord Wolseley's handful of men in whale-boats up the Nile. It was the intention of the late Khedive, partly from military and partly from commercial considerations, to construct a railway exactly on the line of advance subsequently followed by Wolseley. My partner, Mr. Fowler, had the railway set out in 1873, and the works were shortly after commenced. The total length was 550 miles, and the estimated cost, including rolling-stock and repairing-shops, was 4,000,000*l*. Owing to financial difficulties the works were abandoned, but the 64 miles constructed by Mr. Fowler, and the recent extensions of the same by the military, proved of great service to the expedition, even some of the steam launches being taken by railway to save delays at the cataracts.

During the siege of Paris the German forces were dependent upon supplies drawn from their base, and the army requirements were fully met by one line of railway running twelve to fourteen trains per day. Military authorities state that a train load of about 250 tons is equal to two days' rations and corn for an army corps of 37,000 men and 10,000 horses. The military operations in Egypt have proved that, even in the heart of Africa, railways, steamboats, electric lights, machine guns, and other offspring of mechanical science, are essential ingredients of success.

Members of this Section, who visited the United States last year not for the first time, could hardly have failed to notice that American and European engineering practice are gradually presenting fewer points of difference. Early American iron railway bridges were little more than the ordinary type of timber bridge done into iron, and the characteristic features, therefore, were great depth of truss, forged links, pins, screw-bolts, round or rectangular struts, cast-iron junction pieces, and, in brief, an assemblage of a number of independent members more or less securely bolted together, and not, as in European bridges, a solidly riveted mass of plates and angle-bars. At the present moment the typical American bridge is distinctly derived from the grafting of German practice on the original parent stock. Pin connections are still generally used in bridges of any size, but the top members and connections are more European than American in construction, whilst for girders of moderate span, such as those on the many miles of elevated railway in New York, riveted girders of purely European type are admittedly the cheapest and most durable. From my conversations with leading American bridge builders, I am satisfied that their future practice and our own will approach still more nearly. We should never think of building another Victoria tubular bridge across the St. Lawrence, or repeat the design of the fallen Tay bridge, nor would they again imitate in iron an old timber bridge, or repeat the design of the fallen Ashtabula bridge. In one respect the practice in America tends to the production of better and cheaper bridges than does our own practice, and it is this: each of the great

bridge-building firms adopts by preference a particular type design, and the works are laid out to produce bridges of this kind. It is an old adage that practice makes perfect, and by adhering to one type, and not vaguely wandering over the whole field of design, details are perfected and a really good bridge is the result. Engineers in America therefore need only specify the span of their bridge, and the rolling load to be provided for, with certain limiting stresses, and they can make sure of obtaining a number of tenders from different makers of bridges, varying somewhat in design, but complying with all the requirements. With us, on the other hand, it is too often the privilege of a pupil to try his 'prentice hand on the design for a bridge, and it is no wonder, therefore, that many curious bits of detail meet the eye of an observant foreigner inspecting our railways.

The magnificent steel wire rope suspension bridge of 1,600 feet span built by Roebling across the East River at New York well marks the advanced state of mechanical science in America as regards bridge building. It is worthy of note that, at the second meeting of the British Association, held so long back as 1832, there was a paper on suspension bridges, and the author entreated the attention of the scientific world, and particularly of civil engineers, to the serious consideration of the question: How far ought iron to be hereafter used for suspension bridges, since a steel bridge of equal strength and superior durability could be built at much less cost? 'I earnestly call upon the ironmasters of the United Kingdom,' said he, 'to lose no time in endeavouring to solve this question.' In this, as in many other engineering matters, Americans have given us a lead. America is, indeed, the paradise of mechanics. When the British Association was inaugurated, years ago, there was, I believe, no intention to have a section for the discussion of mechanical science. Possibly it may have been considered too mean a branch. Even the usually generous Shakespeare speaks contemptuously of 'mechanic slaves, with greasy aprons, rules, and hammers;' and our old friend Dr. Johnson's definition of 'mechanical' is 'mean, servile.' We have lived down this feeling of contempt, and the world admits that the 'greasy apron' is as honourable a badge as the priest's cassock or the warrior's coat of mail, and has played as important a part in the great work of civilising humanity and turning bloodthirsty savages into law-abiding citizens.

As I have had occasion to refer to Canada and America in the course of my remarks, I cannot refrain from expressing the high appreciation which I am sure every member of this Section entertains of the cordiality and warmth of our reception on the other side of the Atlantic last year. Such incidents make us forget that differences have ever existed between the two countries. I was amused the other day, on reading in Dr. Doran's 'Annals of the Stage' that, in the year 1777, the theatrical company from Edinburgh was captured on its voyage to Aberdeen by an American privateer, and taken off heaven knows where, for it did not turn up again. This, you will say, was a long time ago; but, if you glance through the speeches of our present gracious Sovereign, you will find one in which her Majesty speaks with 'deep concern' of insurrection in Lower Canada, and of hostile incursions into Upper Canada by certain 'lawless inhabitants' of the United States of North America.

This is strange reading, after our last year's experience. Gentlemen, I may not have carried you with me in some things I have said, but I think you will all agree with me in this: that the statesmen who should suffer any slight difference of opinion to develop into a serious breach between ourselves and our brethren in Canada and cousins in America would, to quote the words of Burke, 'far from being qualified to be directors of the great movements of this empire, be not fit even to turn a wheel in the machine.'

The following Papers were read:—

1. *The New Tay Viaduct. By* CRAWFORD BARLOW, *B.A., M.Inst.C.E.*

2. *The Forth Bridge Works.* *By* ANDREW S. BIGGART, *C.E.*

See Reports, p. 873.

FRIDAY, SEPTEMBER 11.

The following Papers were read:—

1. *The American System of Oil Pipe Lines.* *By* J. H. HARRIS.

---

2. *The Movement of Land in Aberdeen Bay.* *By* W. SMITH.

---

3. *On Shallow-draught Screw-steamers for the Nile Expedition.* *By* J. T. THORNYCROFT, *M.Inst.C.E.*

A special feature of these steamers for use in shallow waters is the form of the hull in the neighbourhood of the propellers, it being such as to maintain a volume of water, like a wave, over the propellers, even though they should extend above the water-line of the vessel. The author demonstrated the serviceableness of such a form as early as 1875.

The second special feature is the kind of propeller used. It resembles a screw, but is placed in a tube having guides to direct the stream aft, and a conical body to contract the area of stream.

The principal dimensions of the Nile boats are given below:

	ft.	in.
Length of hull at water-line	140	0
Beam moulded	21	0
Load draught	2	3
Displacement	93·6 tons	

With a light draught of 2 feet aft, $67\frac{1}{2}$ tons displacement, a speed of 15·1 knots was obtained, while at the load draught trial, 2 feet 3 inches, the displacement being 93·6 tons, a speed of 14·17 knots was obtainable with an I H.-P. of 390. The displacement coefficient was 150.

The vessel is arranged to carry guns on its upper deck, which is supported on bullet-proof houses. On the fore part of the upper deck is a bullet-proof conning tower containing a steam steering engine.

The hull is of steel divided into water-tight compartments; the engines are of the same model as used in the torpedo-boats by the author's firm, and the boats are fitted with triple rudders in order to increase the steering power for the special purposes for which they are intended.

---

4. *The Sphere and Roller Friction Gear.* *By* Professor H. S. HELE SHAW.

The author described before Section A last year the principles involved in the action of the 'sphere and roller' mechanism, a complete investigation of which is being published in the Philosophical Transactions of the Royal Society. Since that time the above principles have been further applied, the results of which may be seen in the mathematical instrument section and in the transmission of power section of the Inventions Exhibition. The object of the author in the present paper is to speak only of the latter application, giving the results of actual trial and a description of a new arrangement which is being made on a still larger scale.

The author, first by means of diagrams, briefly explained the principles of the mechanism, in which a change of the imaginary axis of revolution of the sphere is

effected by merely altering the position of one frame containing a set of wheels or rollers in contact with the sphere. The result of this change is that the relative velocity of two given rollers in a second or fixed frame are correspondingly altered. One of these latter wheels or rollers being employed as a driver, motion can be imparted to the sphere by frictional contact with it, and thus the second wheel or roller in the same frame can be employed as a follower and driven at any required velocity relatively to the first. After unsatisfactory experiments with a heavy ball, whereby force closure was substituted for pair closure, it was determined to return to the pair-closed arrangement, in which the necessary frictional contact was obtained by the pressure of suitably placed rollers, and the author's brother, Mr. Edward Shaw, designed and executed a machine which it was calculated would, at not excessive velocities, transmit nearly 2 H.-P. This was given the form of a sack hoist, which has been for some time in operation at the Exhibition. The author then described the details of this machine by means of diagrams. The action is in most respects highly satisfactory, there being almost perfectly silent action and an absence of all noise and vibration. By means of one small handle, which simply causes the movable frame to roll round on the sphere, and therefore is turned with scarcely any appreciable effort, not only is the hoisting of a small sack performed at any required speed, but the same handle when moved so as to cause the axis of rotation to pass between the driver and follower, instead of on one side of them, causes a reversal of motion and consequent lowering of the sack at any required speed. In the intermediate position, i.e. when the axis of rotation of the sphere passes through the point of contact of the follower, no motion ensues. Thus all necessity either for a starting and stopping gear or for a brake is avoided, and the whole operation is instantly performed by means of one handle.

Several difficulties had to be overcome, these being:

1. The question of finding suitable material.
2. Heating of bearings with the high speeds and pressures employed.
3. Variable resistance which occurs in different positions of the axis of rotation from want of true point contact.
4. Twisting of the sphere on point of contact with the following roller when the action of rotation passes through that point, and consequent injury of the surfaces in contact when the follower stops.

Difficulties 1 and 2 were completely overcome, the first by using hard elastic surfaces and phosphor bronze, being successfully tried in contact, and also good cast-iron on cast-iron; the second by using Stauffer's lubricators. The third difficulty has been partially and the fourth entirely overcome.

---

5. *On the Employment of the Road Engine in Construction and Maintenance of Roads.*[1] *By* Colonel Innes.

The author first dealt with the historical aspect of road-making, then with the methods which the Kincardine o' Neil District of Aberdeenshire Road Trustees had in previous times adopted in maintaining the roads in that part of the country. They had been faced with so many difficulties that they were now applying steam power in the shape of an ordinary road engine. It had been in operation now for more than a year, and promised to be satisfactory. The method was—The employment of an engine in working a stone breaker, which provides large quantities of metal; the employment of the engine to draw waggons used in applying the metal; and the adaptation of the engine and waggons to act as rollers at the same time as they are employed in applying the metal, thus applying the metal, rolling it into solidity, and leaving a thoroughly finished surface. They had to deal with insufficiently constructed roads, and roads having the appearance of being well constructed, but when subjected to heavy locomotive engine traffic where the subsoil was soft they gave way. The engine and waggons in applying the metal found out all the weak places, and the yielding surface was coated with metal until it has

[1] Printed *in extenso* in the *Contract Journal*, September 28, 1885.

uniform strength with the rest of the roads. He proceeded to describe the engine, the stone breaker, and the working plant. The wheels of the waggons broke gauge, and by an adjustment of the coupling the eight wheels were made to cover a surface of eight feet wide, or, allowing for overlapping, would effectually roll a surface of from six to seven feet. The total cost of the plant was 1,104*l.* and this was inclusive of 309*l.* for the stone breaker and the van, so that the cost of the plant specially required was limited to the engine and waggons, or a cost of 795*l.* For a durable surface of road hand-broken metal was better, but the cost was considerably greater, being 2*s.* 8*d.* per cubic yard: while engine-broken metal cost 1*s.* 10*d.*, and this included cost of quarrying. He concluded by saying that it was seldom that so entirely novel system could be set inoperation without some partial failures or disappointments, but this had been an exception. It worked even better than was anticipated, the means were seen clearly whereby some details, which they left over to await experience, could be perfected, and they looked forward with confidence by means of this system to reconstructing and maintaining all the main lines of roads in the district, and to the increasing traffic which they had to carry without any additional cost to the ratepayers. And this too in a district where the condition of the roads was most unsatisfactory, and the prospect of improving them hopeless without an expenditure, which it was difficult to contemplate providing for.

SATURDAY, SEPTEMBER 12.

The Section did not meet.

MONDAY, SEPTEMBER 14.

The following Papers were read:—

1. *Electric Lighting and the Law. By* Dr. LEWIS EDMUNDS.

The author adduced evidence to show that the stagnation in the electric lighting industry arises, not from the fact that electric lighting cannot prove remunerative as a commercial undertaking if left to its own free development, as most other industries have been, but because electric lighting under the conditions imposed by Act of Parliament is commercially impossible. The public supply of electricity is now regulated by the Electric Lighting Act of 1882, and so long as that Act remains unamended or unrepealed, there is no opportunity for great development in electric lighting as a matter of public supply.

Directly the unfortunate companies sought an Act to give them the necessary powers there was a great outcry about monopoly, and the success of the present gas and water companies was held up to the public as the result of an *unfair* monopoly. Many people seemed to forget that the existing companies are the successful survivors of a large number, a considerable proportion of which have proved great losses. If there had not been some inducement to the original investors in the way of future profit we should probably have had many large towns still without a proper supply of gas and water. The Legislature seemed to forget how much we owe to the encouragement of private enterprise in this country, and that we are indebted to it for a better supply of gas and water than any other country in the world.

The electric lighting companies would not have any ground for complaint if the conditions imposed upon them by the Act had been a reasonable *quid pro quo* for the privilege of taking up roads or footpaths for their own purposes and the monopoly (more or less) of supplying a district. The fault of the Act is in placing such stringent conditions on persons supplying electricity, and in asking so much of them as to deprive them of opportunity to realise an adequate return for their outlay. The public grant certain concessions to a company, and it is just and

equitable that conditions should be imposed for the proper performance of the business in respect of which the privileges are obtained. If the public ask too much no one will take the other side of the bargain, and the Legislature extinguishes what it meant to regulate.

The section of the Act which has done nearly all the harm is section 27, which relates to compulsory purchases by the local authority of undertakings within the Act.

Shortly the section amounts to this. The local authority can, after 21 years, or at their option, after the expiration of any subsequent period of seven years, purchase compulsorily the undertaking within their jurisdiction, at the fair market value of the lands, buildings, works, materials, and plant merely as such without any addition, in respect of compulsory purchase or goodwill, or any profits made in the past, or to be made in the future.

If therefore the enterprise is unsuccessful it will be left on the investor's hands.

If successful, it will be compulsorily bought by the Local Authority for the mere value of the plant then in actual use, just when it has become a valuable property and he is beginning to reap the full advantage of his investment, which may be at the end of 21 years or of any subsequent seven year period.

By not giving the promoters any real interest in the undertaking, it would prevent any large expenditure on works, with a view to a permanent and lasting installation; their only object would be to make the maximum profit from the business while it lasted without any regard to the future.

The position stands somewhat thus:—

Parliament does not want to give anyone but the local authority a monopoly for more than 21 years.

It will not pay investors unless they get a monopoly for a much longer period.

The local authorities are not fit persons to undertake these speculative enterprises, even if they were justified in using the ratepayers' money for doubtful results.

The consequence is that, in its anxiety to prevent a monopoly, the Legislature has entirely deprived the general public of the comfort and security and other advantages which the electric light offers over all other forms of illumination.

---

2. *On an Electric Safety Lamp for Miners.* *By* J. Wilson Swan, *M.A.*

No mere portable electric lamp being dependent upon extraneous wire connection, of which some exist under the name of 'Miners' lamps,' can be truly called a safety-lamp.

A hand-lamp, detached and portable, more or less like the ordinary safety-lamp, is an absolute necessity in order to comply with the conditions implied in the term 'Electric Safety-lamp.'

The subject of the present paper fulfils those conditions. It consists of two parts; the lamp proper, and the battery to feed it. The combined apparatus weighs only $6\frac{3}{4}$ lbs.; and the cylindrical case containing the cells measures 8 by 4 inches.

The battery consists of seven cells, and is thus constructed:—The core is a lead wire surrounded by peroxide of lead. This is covered by a wrapping of cloth, outside which, and filling the space between the oxide cylinder and the interior lead lining of the containing tube, is a packing of lead filament. The lead filament is in contact with the lead lining, and that with a strip of lead which forms one of the outward conductors; the lead wire forming the core of the oxide cylinder being the other conductor. The electrolyte is dilute sulphuric acid; adhesion to the lead filament prevents the liquid from spilling, if the battery is inclined.

The terminals are attached to two elastic strips of brass, and these hold the lamp between them with a slight end pressure, in a simple manner, so as to be easily removable.

The lamp, of a half-candle power, probably requires less current than any lamp hitherto made, viz. ·14 of an ampère; the electro-motive force being 12 to 13 volts. The cells can store sufficient energy to sustain the lamp during ten to twelve hours.

Contact is made and broken within a small cavity in the switch plate containing a single drop of oil. Even without this precaution, there is not the slightest danger of ignition of explosive gas by a spark produced at the switch on opening the circuit.

To charge, say five hundred lamps would neither be complicated nor costly; a dynamo absorbing three to four H.P. would suffice. The cells would be ranged on benches in front of fixed wires from the dynamo; and these would be so fitted with coupling plugs, that the connecting of several hundred batteries would be the work of a very short time.

The cost of the renewal of the electric would probably be about the same as the cost of filling, cleaning, and keeping in repair Davy lamps; or about *2d.* per lamp per week. The supply of oil for ordinary safety lamps costs another *2d.* per week; which would fully cover the cost of charging the batteries for the electric light.

Here, then, is a miner's lamp, to which the appellation of '*Safety*' may be given without any reservation; and one which is free from even the suspicion of causing an explosion of fire-damp. Besides its safety, there is one other advantage of occasional importance. Oil lamps require air more or less pure to support the combustion of the oil. There are, unfortunately, times, after an explosion of fire-damp, when the air of the pit is so foul that no oil lamp will burn in it. With this electric lamp, which requires no air, and with a Fleuss apparatus for breathing, the work of exploration might be carried on, and this, it is reasonable to hope, would be attended with the saving of life.

3. *On the Strength of Telegraph Poles. By* W. H. PREECE, *F.R.S., M.Inst.C.E.*—See Reports, p. 853.

---

4. *On Domestic Electric Lighting. By* W. H. PREECE, *F.R.S., M.Inst.C.E.*

After referring to the full details of the lighting installation of his house in Wimbledon, given to the section, at the meeting at Montreal, Mr. Preece referred generally to the experiences he had gained during the past twelve months. The secondary batteries, upon which he had mainly relied, exceeded his expectations in the services they rendered. They returned 70 per cent. of the energy put into them, without any apparent diminution whatever in their E. M. F. They showed no signs of deterioration and gave no trouble whatever. He used his gas engine for charging only two days a week. He had experienced no fault with the wiring of his house. He had used only the very best materials, and had attended personally to the insulation of the system. It was periodically tested and found to be good. He referred in severe terms to the cheap and nasty wire, which was so frequently and ignorantly used, and feared that the prejudice against the electric light would increase when failures from this cause arose. None but the very best materials should be used, and the joints should be seen to by experts.

He had devoted considerable attention to the problem of distributing light, and had succeeded so far that, while his rooms were beautifully illuminated, the eye was not irritated by regarding a bright source of light. The lamp he used was a 50-volt 10-candle power glow lamp, and it was, as a rule, so fixed that the eye never saw it. He had arrived at the use of these lamps after careful consideration and many trials of other lamps. They secured greater safety in the leads, and involved less capital in batteries through the use of low E. M. F.

He ran his lamp at an E. M. F. about two per cent less than the nominal E. M. F. He did this to secure long life to his lamps. The breakage had been very small. The E. M. F. and current which will give a lamp a normal life of 1,000 hours and a certain candle power, should be determined by every maker. The sixth power of the current will give the candle power, and the twenty-fifth power the life with any other current. The great advantage of batteries is, that the proper current once determined, can never be exceeded, and thus efficiency is ensured. If lamps are run too low, there is waste of power; if too high, there is waste of lamps. We are now gradually acquiring a thorough knowledge of the

number of volts which should be expended in each lamp to secure the maximum economic efficiency.

He had introduced into the charging lead and into the discharging lead a Ferranti meter, so that he was able to record exactly the quantity of electricity passed through the batteries, and that passed through the lamps. This beautiful meter is based on Ampère's laws, which determine the attraction and repulsion of currents. A small phosphor-bronze vane is immersed in a bath of mercury, through which the current flows radially, fixed in a magnetic field. The mercury rotates and carries with it the vane. The rate of rotation varies directly with the strength of current, and the number of rotations is recorded by a counter, which can be read off directly. So far, he was perfectly satisfied with its performance.

As regards expense, excepting the first cost, he did not find much addition to his expenditure for illumination. His electric light was costing him about 50*l.* a year for gas, wages, oil, and lamps. It was the cheapest luxury he indulged in. Its great advantages were the comfort and cheerfulness it engendered; and as cheerfulness was the main element of health, he thought that the electric light would prove a serious rival to the doctor. There was no one who valued health and comfort who should neglect to apply the electric light to his home when it was brought, as it has been by the success of the secondary battery, within his means. It was said that he, as an expert, could make things go which would fail in ordinary hands; but he instanced several cases where coachmen, butlers, gardeners, and grooms had been found perfectly competent and intelligent enough to attend to everything.

---

5. *On a System of Periodic Clock Control on Telephone or Telegraph Lines.* *By* Professor W. F. Barrett, *F.R.S.E.*

The expense of maintaining separate lines for the sole purpose of synchronising the clocks in a town led the author to devise an arrangement some four years ago whereby telephone and telegraph lines could be utilised for clock control and also for burglar and fire alarm. Every subscriber to a telephone exchange is, by this means, enabled to have a main clock in his house kept in true time with the standard clock at the Telephone Exchange. This main clock at certain times switches off the telephone receiver and puts into circuit the electro-magnetic arrangement whereby the clock is synchronised. The method adopted for this purpose is a modification of Ritchie's system of hourly control, with a semaphore attached to indicate the true time to a fraction of a second. This main controlled clock, by a simple contact arrangement fitted to a disc on the arbor of the minute wheel, distributes time true to a minute throughout the establishment. This is accomplished by an electro-magnetic minute clock of novel and very simple construction, which however requires a diagram to describe. The main clock also switches off the telephone circuit during the night, and puts in its place the fire alarum circuit of the house, and also the circuit passing through a safe or air tight case, which circuit is instantly closed whenever a burglar attempts to force the safe. In this way the central exchange is automatically 'rung up,' and the correct house indicated whenever a fire breaks out or a burglar breaks in. The author stated he had had this system at work very satisfactorily for some time in his own laboratory.

---

6. *Electric Lighting at the Forth Bridge Works.* *By* James N. Shoolbred, *B.A.*, *M.Inst.C.E.*—See Reports, p. 879.

---

7. *On the Development of the Pneumatic System as applied to Telegraph purposes.* *By* J. W. Willmot.

It is probably not generally known by what means telegraphic messages are collected from the branch offices in large towns, and conveyed to the central office for transmission by wire. This service is performed by means of pneumatic tubes,

through which 'carriers' containing the actual written messages are propelled. The system was first introduced by Mr. L. Clark in 1854, who employed vacuum, drawing the carriers in one direction only. The first tube which came into operation was laid for the Electric Telegraph Company between their office in Lothbury and their branch office at the Stock Exchange. This tube was in continuous use for over twenty years and was in good condition when raised.

About the year 1866 Mr. C. F. Varley applied compressed air for propelling the carriers in the opposite direction from that in which they were drawn by vacuum, and very ingenious valves were designed by him for effecting the change from vacuum to pressure.

With each of the foregoing systems it was necessary after the transmission of a carrier to restore the pressure in the tube to the normal atmospheric pressure before another carrier could be despatched. This caused considerable delay and loss of engine-power.

In 1870 the author designed the double sluice valve which is now in general use, and by means of which carriers can be despatched continuously without stopping the flow of air in the tube.

The employment of pneumatic tubes in London has been continually increasing until the system, which in 1854 was represented by one 6 H.P. engine working a single tube a few yards in length, at the present time comprises four 50 H.P. engines (each indicating 130 H.P.) and forty-nine tubes, the aggregate length of which exceeds twenty-seven miles. These figures are exclusive of over a mile in short lengths of house tubes also worked by the engines, as well as of over a dozen hand-worked tubes in various metropolitan offices. The use of pneumatic tubes, however, has not been restricted to London alone, for in the provincial cities and towns there are sixty-three tubes which, with the London tubes, bring the total length of engine-worked tubes to upwards of thirty-nine miles. To these should be added ninety-five shorter hand-worked tubes. With the air-pressure employed an approximate speed of one mile in seventy seconds is attained in tubes not exceeding a mile in length. The speed varies inversely as the square of the length of the tube. The pipes generally employed are of lead, having an internal diameter of $2\frac{1}{4}$ inches.

At Liverpool a very complete pneumatic system has lately been installed. The number of tubes has been increased from eight to fourteen and three 30 H.P. beam engines (each indicating up to 90 H.P.) have been erected. These engines were designed and constructed under the personal supervision of the author, and were made by Messrs. Easton and Anderson of Whitehall Place, London, and Erith, Kent. The pumps are so arranged that either set can either exhaust or compress air. Two engines are sufficient for the present requirements, the third being spare in case of breakdown.

TUESDAY, SEPTEMBER 15.

The following Report and Papers were read :—

1. *Report of the Patent Law Committee.*—See Reports, p. 695.

2. *Autographic Apparatus for Machines for Testing Materials. By* Professor W. C. Unwin, *M.Inst.C.E.*

With the increasing use of steel in construction, the necessity of regular and systematic testing of the elastic properties of materials has become much more urgent. Rough bending and temper tests furnish, it is true, useful information as to the quality of steel. But no procedure furnishes information so reliable and accurate as a breaking test, carried out by means of a suitable machine; nor can the quality of the material be specified in any other way so definitely, as by requiring

that its breaking stress and its elongation or contraction should lie between assigned limits.

In the ordinary testing of materials, we observe the loads successively imposed and the corresponding deformation of the bar. If such a series of observations is plotted with the loads for ordinates and the elongations for abscissæ, and the points so found are connected by a curve, we get a stress and strain diagram showing at a glance the whole of the observations and indicating by its form the character of the material.

Now it is easy to see that such a diagram, like the indicator diagram of a steam engine, may be drawn autographically by the machine itself, and that the autographic diagram will have some advantages over the diagram plotted from discontinuous observations. It will be a continuous record at all stages of the test, it will be free from accidental errors of recording, and at all events it will save a great deal of trouble in making numerous successive observations.

The first autographic apparatus for testing machines was probably that attached by Thurston to his Torsion apparatus. But a Torsion machine is not usually employed in engineering tests. Not long after Polmeyer constructed a testing machine for tension tests with an autographic arrangement attached. This the author saw at Dortmund in 1883. Since then, Fairbanks in America, and Wicksteed in this country, have constructed autographic apparatus for ordinary testing machines.

The author designed an apparatus for recording tension tests in January 1883. That apparatus gave a diagram two feet square. Since then he has constructed a smaller and handier apparatus which is placed on the table.

In the author's testing machine the loading of the specimen is effected by a single weight of a ton travelling along a lever or steelyard about 20 feet long. The motion of the screw which drives the travelling weight is transferred exactly to a brass cylinder like the paper cylinder of a steam-engine indicator. The amount of the rotation of this is, therefore, exactly proportional to the load on the specimen. The pencil slides at the same time axially with a motion proportional to the extension of the specimen. This motion is obtained from a very thin wire, attached to the specimen, and strained over pullies, so that the motion of the pencil is double the actual extension. The wire is kept strained to a given tension by a weight of two or three ounces. By suitable choice of position of the autographic apparatus on the testing machine, the small vertical movement of the specimen in testing has no sensible influence on the record. It appears from check measurements that the record of the load is exact, and that of the extension has an error of at most $\frac{1}{100}$th of an inch.

The accuracy of the record of extension depends mainly on two arrangements. (1) The selection of a position for the recording apparatus such that no horizontal movement other than that to be recorded is communicated to the wire. (2) On the use of an extremely fine wire, which can be strained to straightness and kept free from bends by a very small weight. The form of the clips which define the length on which the extension is measured is also of importance. In the clips shown the specimen is held between a plane, a knife edge and a point, so that the clips are rigid as regards any tilting on the specimen, and at the same time precisely define the length on which the measurement is made.

3. *Notes on Mild Steel.* *By* G. J. GORDON.

The first note was with reference to the corrosion of steel, which was shown to have now been proved by experience to be about the same as for wrought iron.

2nd. It was pointed out that shearing thick plates had the remarkable effect of rendering them cold short, and that this was completely cured by either annealing the plates or by planing off the rough edges left by the shears.

3rd. It was pointed out that the tendency of users of steel was towards employing that of higher tensile strains, and that there was no reason why this should not be done provided the same ductility and toughness are insisted on, as in the case of the milder steel now in use.

4th. The question of the use of thick plates for boilers was discussed, and the results of a series of experiments were given, which go to show that if the material is carefully made and tested, heated in proper furnaces, and bent without putting any undue strains upon them in the boiler maker's shop, it was just as safe to use plates for boilers from 1″ to $1\frac{1}{2}$″ thick, and weighing from 1 ton 10 cwt. to 2 tons 10 cwt., as it is to use those from $\frac{3}{8}$″ to 1′ thick and weighing from 10 cwt. to 1 ton 10 cwt.

4. *The Diminution of Casualties at Sea.* *By* Don Artùro de Marcoartu.

The author in his paper made the following proposals:—1. That vessels be supplied with apparatus to communicate with and to telegraph to each other and to the nearest coast the weather and sea encountered by them; 2. That the steamers give more detailed reports about the weather and sea as soon as they arrive on both coasts, but more especially on the American coast, to the Navy Department and to the U.S. Signal Service; 3. That a special, regular, and permanent service be established on the American coast, supplied with the requisite means to receive all reports, and to transmit to Europe several warnings each day about the reports collected and the predictions bearing on the navigation; 4. That from the European coasts be communicated daily to the American coasts the state of the weather and sea for comparison with the predictions and for the continuous study of the sea and weather.

For advancing meteorological knowledge, and in the interest of navigation, he recommended the establishment of two more cables—one to connect Iceland and the Faroes with Europe, the other to connect Azores and Bermuda with Europe and America; as all the submarine cables connecting North America and North Europe have not intermediate stations on the middle Atlantic, and the great extent of the ocean renders reporting impossible.

In the charts of relative storm frequency in the Northern Hemisphere, prepared by the American Signal Service, and published only a few months ago, it is shown in the annual average of the relative storm frequency during twenty-one years, from 1864 to 1884, that the sea is most calm between the meridian 40° and 9° (near to the Iberian Peninsula), and from latitude 40° at the first meridian to latitude 46° at long. 1°; and stormy towards the latitudes of Newfoundland, and ascending from their parallels to the north of Ireland.

The last limit of the most frequent icebergs, according to the observations collected by the Hydrographer of the United States Navy Department, was near 40° latitude; and therefore the track from the United States to Lisbon is to the south of the icebergs.

Professor Graham Bell published a few months ago the results of some experiments to detect by echo the proximity of vessels and wrecks. The experiments were made on the River Patapsco, about seven miles from Baltimore. The apparatus employed consisted of a musket, to the muzzle of which a speaking-trumpet was attached. From this musket blank cartridges were fired when passing vessels, and after a longer or shorter time, according to the distance of the vessels, an echo was returned.

The author called attention years ago to the great power of ice for reflecting sound, and believes the possibility of obtaining an echo from an iceberg, when in dangerous proximity to a ship, is worth a trial at sea. Both apparatus, the thermopiles combined with the trumpet, and the steam-whistle and siren, ought to be used; but it is better to select a route away from bergs, fields, and fogs, which have caused the loss of so many vessels. Parry says, in the account of his Polar Expedition, that two men conversed distinctly at a distance of a mile and a quarter.

Fires.

To lessen the risk from fire 'automatic sprinklers for fire extinction' and 'fire alarms' are required in some parts of the ship, especially in connection with inflammatory goods.

The principle of 'fire alarms' and 'automatic sprinklers' is well known. In the fire alarms a sudden rise of temperature expands a spring, which moves a screw or another piece to complete an electrical circuit, and the bell or alarm is sounded. The principle of the automatic sprinkler is a pipe of water covered or sealed by a metal cap secured only by soldering some alloys melting at, say, 150 degrees Fahrenheit. When this temperature is reached, the cover is melted, and the water thrown with the volume required. These automatic sprinklers are coming into general use in the mills of the United States. As the cost of fixing the alarm and the sprinkler is small, the combination of both appliances is desirable.

Collisions.

To avoid collision with other vessels, the International Code prescribes the use of the steam-whistle at intervals of not more than two minutes.

In fog the only practical signal to-day is sound; but the existing signals must be improved and an international code of signals showing at once the direction of the approaching vessel introduced. Many telegraphic codes can be suggested for that purpose.

The speed of steamers in a fog must be fixed according to the strength of the alarm sounds and the power of controlling the movements of the vessel. If the alarm is heard at long distances and is sounded frequently, and the control of the vessel is easy, it is possible to proceed at greater speed than if the alarm were less well heard, not sounded so frequently, and the management of the ship difficult.

Automatically, and at the same time that the direction of the helm is changed to avoid the collision, the movement must be signalled very distinctly to the other vessels, and the exterior of the ships and the sea must be electrically illuminated. Several appliances can be employed for that purpose, to avert collisions, and to give full light, in the event of a disaster, for rescue.

5. *On the Deep Sea Channel into Swansea Harbour.*[1] *By* Robert Capper.

Describes the cutting of the new deep sea channel into Swansea Harbour, without piers or other protective works, about one-fifth excavated four years ago with hired plant, commencing to dredge in from sea from the centre of Swansea Bay (which did not silt up), and the remainder in the immediate past twelve months, the whole 7,000 feet in length, 200 feet wide at top, 150 feet at bottom, and 14 feet in depth below the old bed of the bay, involving the digging, lifting, and carrying away two million tons of material to a distance of seven miles, gives some account of the geological formation met with, details of the cost, and how the time was spent whilst the work was in hand.

This channel opens Swansea to the largest class of shipping afloat any tide of the year; indeed, turning the neap tides into a blessing, and making the port available as a point of departure for any ship every night of the year at one given hour.

Points out that, at the beginning of the present century, there was scarcely any town of importance in the kingdom that was distant from navigation more than fifteen miles, most of the canals of that period having proved very profitable property. Yet the money spent in docks and harbours around our shores in the last one hundred years to receive the commerce of the whole world, is only double that invested in English canals; our seaports have not kept pace with our shipping, the 500 creeks and harbours, half managed by public bodies, have been allowed to silt up with very few exceptions, opening a wide field for the engineer, as it costs half as much to bring deep water to our doors as to go out to deep water with piers and quays.

Touches upon the deepening of the rivers St. Lawrence, Tyne, Clyde, and Scheldt as examples, the shipping trade of the latter having increased twentyfivefold in recent years.

[1] Published *in extenso* in *Engineering*.

Advocates a return to 'pool' harbours for those silted up, and observes that, although one hundred years ago London absorbed four-fifths of the English shipping trade, it now has only one-fourth; yet it is still the largest port in the world, Antwerp ranking second.

9. *On the British Association Standard Gauge for Small Screws. By* EDWARD RIGG, *M.A.*

At the suggestion of the Mechanical Section a Committee was appointed by the British Association at Southampton in 1882, for the purpose of determining a gauge for the manufacture of the various small screws used in telegraphic and electrical apparatus, in clockwork, and for other analogous purposes. This Committee presented its final report at the Montreal meeting, and it will be of interest to the Section to know that progress has already been made towards the general adoption of the standard series of screws then recommended.

They have been officially adopted by the Telegraph Department of the Post Office, and this step alone may be relied upon to ensure their general adoption by the telegraphic and electric instrument trades in the course of a few years. The entire series of standard taps and dies has not yet been manufactured, but such as have been completed are now on view at the Inventions Exhibition, where they have been awarded a diploma of honour by the Jury Commission.

It will naturally be more difficult to secure their general introduction throughout the clock and watchmaking and other analogous industries, but important help may be expected in reference to these branches, from the fact that in Switzerland, where the system adopted by the British Association originated, an identical series of screws has already secured the support of the leading manufacturers, and the plates and finished screws will very shortly be placed on the market.

SECTION H.—ANTHROPOLOGY.

PRESIDENT OF THE SECTION—FRANCIS GALTON, M.A., F.R.S., President of the Anthropological Institute.

[For Mr. Galton's Address, see p. 1,206.]

THURSDAY, SEPTEMBER 10.

The following Papers were read:—

1. *The Scope of Anthropology, and its relation to the Science of Mind.*[1] *By* ALEXANDER BAIN, *LL.D.*

The author first reviewed the definition and scope of anthropology, as indicated by the leading authorities and by the usage of the British Association. He endeavoured to point out that the bringing together of the six departments—named, respectively, man's place in nature, the origin of man, the classification of races, the antiquity of man, language, and the development of civilisation—does not contribute to the mutual elucidation of the several topics, but merely concentrates into one whole the subjects connected with the higher mysteries of man's origin and destination.

The remainder of the paper was occupied with a survey of the researches conducted in the Section, having in view precise measurements of the bodily and mental characteristics of human beings. The author indicated various lines wherein these researches may be carried out so as to reflect new lights on our intellectual constitution. The examination for delicacy in the sense of colour is not the only important determination relating to vision. Equally, if not more important, is the testing of the sensibility to visual form and magnitude. So in hearing, both musical quality and articulate delicacy are susceptible of exact measurement. Likewise muscular discrimination is an ascertainable quantity, and of great importance in assigning the aptitude for manual skill.

The author also adverted to the research into the conditions and the measure of memory, as wholly within the means of accurate experimental determination; also the important intellectual function of seeing similarity in the midst of diversity, which can be reduced to more or less precision of estimate by suitable means. Taking along with these results the inquiries into the faculties of the lower animals, the author put especial stress upon the number and the delicacy of their senses, as the foundation of every attempt to explain the higher aptitudes. Intelligence commences with the power of discrimination, and increases as that power increases. The record of marvellous feats of exceptional ingenuity is of very little aid in revealing the secrets of the animal mind.

In conclusion, the author urged the admission of psychology, in a more avowed and systematic form, into the Anthropological Section. He would exclude the topics of metaphysical and ethical controversy, and welcome all the experimental researches into the intellectual and emotional regions of the mind.

[1] Printed *in extenso* in the *Journal of the Anthropological Institute*, vol. xv. No. 3, February 1886.

2. *The Index of the Pelvic Brim as a Basis of Classification.*[1] *By* Professor W. Turner, *M.B.*, *F.R.S.*

That the inlet to the human pelvis presented variations in outline, and in the proportions of its conjugate and transverse diameters, has been recognised since the publication by Vrolik in 1826, and by M. J. Weber in 1830, of their important memoirs on the pelvis in certain races of men. In 1866, Zaaijer of Leyden, in his study of the pelvis in women of Java, recognised differences in form in women of that race. He expressed these differences numerically, taking the transverse diameter as = 100, and then multiplying the conjugate diameter by 100, and dividing by the transverse; the numeral so obtained is the index of the pelvic brim or pelvic index.

By applying this method to the pelvis in different races of men, a classification of races based on the index of the brim may be framed. In carrying out this method the male pelvis should especially be studied, as in women the pelvis, for sexual reasons, does not present such wide divergencies in the form of its inlet as in men. To give precision to the classification it will be advisable to employ special terms, and in order as far as possible to bring these terms into accordance with those employed in the classification of crania based on differences in the relations of the length to the breadth of the skull, Greek terms will be employed. Taking the Greek word πέλλα as equivalent to the Latin pelvis, *dolichopellic* will signify a pelvis the conjugate diameter of which is longer than the transverse or closely approaching to it; *platypellic*—a pelvis in which the transverse diameter greatly exceeds the conjugate; *mesatipellic*—a pelvis in which the transverse diameter is not so greatly in excess of the conjugate.

Owing to the comparatively limited number of pelves in the different races of men which have been measured, it may not be possible to fix definitely at present the numerical limits of each of these three groups, but the author assumes that a pelvis with a brim index above 95 is dolichopellic; one with a brim index below 90 is platypellic; one with a brim index between 90 and 95, both inclusive, is mesatipellic. In classing the races of men in one or other of these groups, both the author's own measurements on the pelves of various races and the published measurements of others have been taken. Whilst in some races the observations have been sufficiently numerous to enable one to speak definitely of the mean index of the race, in others, unfortunately, the observations are too few to permit one to do more than give a provisional classification.

The detailed measurements on which this classification is based will be found in the 'Report on the Bones of the Skeleton collected during the Voyage of H.M.S. "Challenger,"' now in the press.

Dolichopellic.	*Mesatipellic.*	*Platypellic.*
Australians.	Negros.	Europeans.
Bushmen.	Tasmanians.	Laplanders?
Hottentots.	New Caledonians.	Esquimaux?
Kaffirs.	Melanesians?	Guanche?
Andamans.	—	Chinese.
Aïno?	—	Mongolians generally?
Malays.	—	American Indians?
Newzealanders?	—	—

When a pelvis has dolichopellic characters it approximates in the relations of its transverse and conjugate diameters to the form of the pelvic brim met with in mammals lower than man. In the dolichopellic Australians, Bushmen, Kaffirs, and Andamanese the sacral length is, on the average, of greater diameter than the breadth, and this also is an animal character.

3. *A Portable Scale of Proportions of the Human Body.* *By* W. F. STANLEY, *F.G.S., F.R.M.S.*

This instrument is a small thin scale or rule of ivory, of about three inches in length and three-quarters of an inch in width. It is divided on each edge of the two faces by lines which represent the proportions of the human body; the male on one side, and the female on the other. The lines are marked with the words, crown, eye, chin, shoulder, teat, navel, hand, &c. The scales of proportions which the lines represent are taken from measurements of the diagrams of the assumed perfect human forms given by John Marshall, F.R.S., F.R.C.S., in his work, 'A Rule of Proportion for the Human Figure.' The opposite edge to that on which the proportions are shown is divided into 100 parts in the same space as the height of the body, the tens being indicated by figures.

The object aimed at by the use of this proportional scale is to compare any person, or statue, or photograph, with the model of perfect form given by Marshall, or to divide the parts of the body in proportional decimals of the whole for description. The method of using the scale is to hold it up before the eye, facing the object at such a distance that the subtended angle from the two extreme lines on the scale may coincide with the crown and sole of the human form observed. When held in this position any intermediate part of the body may be easily compared for its position with that of of the perfect form by looking over the edge of the scale, or be measured off in decimal parts of the total height by looking over the other edge. A very little practice is sufficient to do this with considerable accuracy from life, or from a statue or a photograph. It is suggested that this scale may be very useful in giving approximately exact descriptions of the proportions of people of various races from observation, or of comparing individuals of races among themselves; also for artists and designers for giving the best proportions of the human figure.

The PRESIDENT delivered the following Address:—

THE object of the Anthropologist is plain. He seeks to learn what mankind really are in body and mind, how they came to be what they are, and whither their races are tending; but the methods by which this definite inquiry has to be pursued are extremely diverse. Those of the geologist, the antiquarian, the jurist, the historian, the philologist, the traveller, the artist, and the statistician are all employed, and the Science of Man progresses through the help of specialists. Under these circumstances, I think it best to follow an example occasionally set by presidents of sections, by giving a lecture rather than an address, selecting for my subject one that has long been my favourite pursuit, on which I have been working with fresh data during many recent months, and about which I have something new to say.

My data were the Family Records entrusted to me by persons living in all parts of the country, and I am now glad to think that the publication of some first-fruits of their analysis will show to many careful and intelligent correspondents that their painstaking has not been thrown away. I shall refer to only a part of the work already completed, which in due time will be published,[1] and must be satisfied if, when I have finished this address, some few ideas that lie at the root of heredity shall have been clearly apprehended, and their wide bearings more or less distinctly perceived. I am the more desirous of speaking on heredity, because, judging from private conversations and inquiries that are often put to me, the popular views of what may be expected from inheritance seem neither clear nor just.

The subject of my remarks will be Types and their Inheritance. I shall discuss the conditions of the stability and instability of types, and hope in doing so to place beyond doubt the existence of a simple and far-reaching law that governs hereditary transmission, and to which I once before ventured to draw attention, on far more slender evidence than I now possess.

[1] The data upon which the remarks in this Address are based, together with copies of the illustrated diagrams suspended at the meeting, are published in the *Journal of the Anthropological Institute*, November 1885.—F. G.

It is some years since I made an extensive series of experiments on the produce of seeds of different size but of the same species. They yielded results that seemed very noteworthy, and I used them as the basis of a lecture before the Royal Institution on February 9, 1877. It appeared from these experiments that the offspring did *not* tend to resemble their parent seeds in size, but to be always more mediocre than they—to be smaller than the parents, if the parents were large; to be larger than the parents, if the parents were very small. The point of convergence was considerably below the average size of the seeds contained in the large bagful I bought at a nursery-garden, out of which I selected those that were sown.

The experiments showed further that the mean filial regression towards mediocrity was directly proportional to the parental deviation from it. This curious result was based on so many plantings, conducted for me by friends living in various parts of the country, from Nairn in the north to Cornwall in the south, during one, two, or even three generations of the plants, that I could entertain no doubt of the truth of my conclusions. The exact ratio of regression remained a little doubtful, owing to variable influences; therefore I did not attempt to define it. After the lecture had been published, it occurred to me that the grounds of my misgivings might be urged as objections to the general conclusions. I did not think them of moment, but as the inquiry had been surrounded with many small difficulties and matters of detail, it would be scarcely possible to give a brief and yet a full and adequate answer to such objections. Also, I was then blind to what I now perceive to be the simple explanation of the phenomenon, so I thought it better to say no more upon the subject until I should obtain independent evidence. It was anthropological evidence that I desired, caring only for the seeds as means of throwing light on heredity in man. I tried in vain for a long and weary time to obtain it in sufficient abundance, and my failure was a cogent motive, together with others, in inducing me to make an offer of prizes for family records, which was largely responded to, and furnished me last year with what I wanted. I especially guarded myself against making any allusion to this particular inquiry in my prospectus, lest a bias should be given to the returns. I now can securely contemplate the possibility of the records of height having been frequently drawn up in a careless fashion, because no amount of unbiassed inaccuracy can account for the results, contrasted in their values but concurrent in their significance, that are derived from comparisons between different groups of the returns.

An analysis of the records fully confirms and goes far beyond the conclusions I obtained from the seeds. It gives the numerical value of the regression towards mediocrity as from 1 to $\frac{2}{3}$ with unexpected coherence and precision, and it supplies me with the class of facts I wanted to investigate—the degrees of family likeness in different degrees of kinship, and the steps through which special family peculiarities become merged into the typical characteristics of the race at large.

The subject of the inquiry on which I am about to speak was Hereditary Stature. My data consisted of the heights of 930 adult children and of their respective parentages, 205 in number. In every case I transmuted the female statures to their corresponding male equivalents and used them in their transmuted form, so that no objection grounded on the sexual difference of stature need be raised when I speak of averages. The factor I used was 1·08, which is equivalent to adding a little less than one-twelfth to each female height. It differs a very little from the factors employed by other anthropologists, who, moreover, differ a trifle between themselves; anyhow it suits my data better than 1·07 or 1·09. The final result is not of a kind to be affected by these minute details, for it happened that, owing to a mistaken direction, the computer to whom I first entrusted the figures used a somewhat different factor, yet the result came out closely the same.

I shall explain with fulness why I chose stature for the subject of inquiry, because the peculiarities and points to be attended to in the investigation will manifest themselves best by doing so. Many of its advantages are obvious enough, such as the ease and frequency with which its measurement is made, its practical constancy during thirty-five years of middle life, its small dependence on differ-

ences of bringing up, and its inconsiderable influence on the rate of mortality. Other advantages which are not equally obvious are no less great. One of these lies in the fact that stature is not a simple element, but a sum of the accumulated lengths or thicknesses of more than a hundred bodily parts, each so distinct from the rest as to have earned a name by which it can be specified. The list of them includes about fifty separate bones, situated in the skull, the spine, the pelvis, the two legs, and the two ankles and feet. The bones in both the lower limbs are counted, because it is the average length of these two limbs that contributes to the general stature. The cartilages interposed between the bones, two at each joint, are rather more numerous than the bones themselves. The fleshy parts of the scalp of the head and of the soles of the feet conclude the list. Account should also be taken of the shape and set of many of the bones which conduce to a more or less arched instep, straight back, or high head. I noticed in the skeleton of O'Brien, the Irish giant, at the College of Surgeons, which is, I believe, the tallest skeleton in any museum, that his extraordinary stature of about 7 feet 7 inches would have been a trifle increased if the faces of his dorsal vertebræ had been more parallel and his back consequently straighter.

The beautiful regularity in the statures of a population, whenever they are statistically marshalled in the order of their heights, is due to the number of variable elements of which the stature is the sum. The best illustrations I have seen of this regularity were the curves of male and female statures that I obtained from the careful measurements made at my Anthropometric Laboratory in the International Health Exhibition last year. They were almost perfect.

The multiplicity of elements, some derived from one progenitor, some from another, must be the cause of a fact that has proved very convenient in the course of my inquiry. It is that the stature of the children depends closely on the average stature of the two parents, and may be considered in practice as having nothing to do with their individual heights. The fact was proved as follows:—After transmuting the female measurements in the way already explained, I sorted the children of parents who severally differed 1, 2, 3, 4, and 5 or more inches into separate groups. Each group was then divided into similar classes, showing the number of cases in which the children differed 1, 2, 3, &c. inches from the common average of the children in their respective families. I confined my inquiry to large families of six children and upwards, that the common average of each might be a trustworthy point of reference. The entries in each of the different groups were then seen to run in the same way, except that in the last of them the children showed a faint tendency to fall into two sets, one taking after the tall parent, the other after the short one. Therefore, when dealing with the transmission of stature from parents to children, the average height of the two parents, or, as I prefer to call it, the 'mid-parental' height, is all we need care to know about them.

It must be noted that I use the word parent without specifying the sex. The methods of statistics permit us to employ this abstract term, because the cases of a tall father being married to a short mother are balanced by those of a short father being married to a tall mother. I use the word parent to save a complication due to a fact brought out by these inquiries, that the height of the children of both sexes, but especially that of the daughters, takes after the height of the father more than it does after that of the mother. My present data are insufficient to determine the ratio satisfactorily.

Another great merit of stature as a subject for inquiries into heredity is that marriage selection takes little or no account of shortness or tallness. There are undoubtedly sexual preferences for moderate contrast in height, but the marriage choice appears to be guided by so many and more important considerations that questions of stature exert no perceptible influence upon it. This is by no means my only inquiry into this subject, but, as regards the present data, my test lay in dividing the 205 male parents and the 205 female parents each into three groups—tall, medium, and short (medium being taken as 67 inches and upwards to 70 inches), and in counting the number of marriages in each possible combination between them. The result was that men and women of contrasted heights, short

and tall or tall and short, married just about as frequently as men and women of similar heights, both tall or both short; there were 32 cases of the one to 27 of the other. In applying the law of probabilities to investigations into heredity of stature, we may regard the married folk as couples picked out of the general population at haphazard.

The advantages of stature as a subject in which the simple laws of heredity may be studied will now be understood. It is a nearly constant value that is frequently measured and recorded, and its discussion is little entangled with considerations of nurture, of the survival of the fittest, or of marriage selection. We have only to consider the mid-parentage and not to trouble ourselves about the parents separately. The statistical variations of stature are extremely regular, so much so that their general conformity with the results of calculations based on the abstract law of frequency of error is an accepted fact by anthropologists. I have made much use of the properties of that law in cross-testing my various conclusions, and always with success.

The only drawback to the use of stature is its small variability. One-half of the population with whom I dealt varied less than 1·7 inch from the average of all of them, and one-half of the offspring of similar mid-parentages varied less than 1·5 inch from the average of their own heights. On the other hand, the precision of my data is so small, partly due to the uncertainty in many cases whether the height was measured with the shoes on or off, that I find by means of an independent inquiry that each observation, taking one with another, is liable to an error that as often as not exceeds $\frac{2}{3}$ of an inch.

It must be clearly understood that my inquiry is primarily into the inheritance of different degrees of tallness and shortness. That is to say, of measurements made from the crown of the head to the level of mediocrity, upwards or downwards as the case may be, and not from the crown of the head to the ground. In the population with which I deal the level of mediocrity is $68\frac{1}{4}$ inches (without shoes). The same law applying with sufficient closeness both to tallness and shortness, we may include both under the single head of deviations, and I shall call any particular deviation a 'deviate.' By the use of this word and that of 'mid-parentage' we can define the law of regression very briefly. It is that the height-deviate of the offspring is, on the average, two-thirds of the height-deviate of its mid-parentage.

If this remarkable law had been based only on experiments on the diameters of the seeds, it might well be distrusted until confirmed by other inquiries. If it were corroborated merely by the observations on human stature, of which I am about to speak, some hesitation might be expected before its truth could be recognised in opposition to the current belief that the child tends to resemble its parents. But more can be urged than this. It is easily to be shown that we ought to expect filial regression, and that it should amount to some constant fractional part of the value of the mid-parental deviation. It is because this explanation confirms the previous observations made both on seeds and on men that I feel justified on the present occasion in drawing attention to this elementary law.

The explanation of it is as follows. The child inherits partly from his parents, partly from his ancestry. Speaking generally, the further his genealogy goes back, the more numerous and varied will his ancestry become, until they cease to differ from any equally numerous sample taken at haphazard from the race at large. Their mean stature will then be the same as that of the race; in other words, it will be mediocre. Or, to put the same fact into another form, the most probable value of the mid-ancestral deviates in any remote generation is zero.

For the moment let us confine our attention to the remote ancestry and to the mid-parentages, and ignore the intermediate generations. The combination of the zero of the ancestry with the deviate of the mid-parentage is that of nothing with something, and the result resembles that of pouring a uniform proportion of pure water into a vessel of wine. It dilutes the wine to a constant fraction of its original alcoholic strength, whatever that strength may have been.

The intermediate generations will each in their degree do the same. The mid-deviate of any one of them will have a value intermediate between that of the mid-

parentage and the zero value of the ancestry. Its combination with the mid-parental deviate will be as if, not pure water, but a mixture of wine and water in some definite proportion had been poured into the wine. The process throughout is one of proportionate dilutions, and therefore the joint effect of all of them is to weaken the original wine in a constant ratio.

We have no word to express the form of that ideal and composite progenitor, whom the offspring of similar mid-parentages most nearly resemble, and from whose stature their own respective heights diverge evenly, above and below. He, she, or it, may be styled the 'generant' of the group. I shall shortly explain what my notion of a generant is, but for the moment it is sufficient to show that the parents are not identical with the generant of their own offspring.

The average regression of the offspring to a constant fraction of their respective mid-parental deviations, which was first observed in the diameters of seeds, and then confirmed by observations on human stature, is now shown to be a perfectly reasonable law which might have been deductively foreseen. It is of so simple a character that I have made an arrangement with one movable pulley and two fixed ones by which the probable average height of the children of known parents can be mechanically reckoned. This law tells heavily against the full hereditary transmission of any rare and valuable gift, as only a few of many children would resemble their mid-parentage. The more exceptional the gift, the more exceptional will be the good fortune of a parent who has a son who equals, and still more if he has a son who overpasses him. The law is even-handed; it levies the same heavy succession-tax on the transmission of badness as well as of goodness. If it discourages the extravagant expectations of gifted parents that their children will inherit all their powers, it no less discountenances extravagant fears that they will inherit all their weaknesses and diseases.

The converse of this law is very far from being its numerical opposite. Because the most probable deviate of the son is only two-thirds that of his mid-parentage, it does not in the least follow that the most probable deviate of the mid-parentage is $\frac{3}{2}$, or $1\frac{1}{2}$ that of the son. The number of individuals in a population who differ little from mediocrity is so preponderant that it is more frequently the case that an exceptional man is the somewhat exceptional son of rather mediocre parents, than the average son of very exceptional parents. It appears from the very same table of observations by which the value of the filial regression was determined, when it is read in a different way, namely, in vertical columns instead of in horizontal lines, that the most probable mid-parentage of a man is one that deviates only one-third as much as the man does. There is a great difference between this value of $\frac{1}{3}$ and the numerical converse mentioned above of $\frac{3}{2}$; it is four and a half times smaller, since $4\frac{1}{2}$, or $\frac{9}{2}$, being multiplied into $\frac{1}{3}$, is equal to $\frac{3}{2}$.

Let it not be supposed for a moment that these figures invalidate the general doctrine that the children of a gifted pair are much more likely to be gifted than the children of a mediocre pair. What it asserts is that the ablest child of one gifted pair is not likely to be as gifted as the ablest of all the children of very many mediocre pairs. However, as, notwithstanding this explanation, some suspicion may remain of a paradox lurking in these strongly contrasted results, I will explain the form in which the table of data was drawn up, and give an anecdote connected with it. Its outline was constructed by ruling a sheet into squares, and writing a series of heights in inches, such as 60 and under 61, 61 and under 62, &c., along its top, and another similar series down its side. The former referred to the height of offspring, the latter to that of mid-parentages. Each square in the table was formed by the intersection of a vertical column with a horizontal one, and in each square was inserted the number of children out of the 930 who were of the height indicated by the heading of the vertical column, and who at the same time were born of mid-parentages of the height indicated at the side of the horizontal column. I take an entry out of the table as an example. In the square where the vertical column headed[1] 69– is intersected by the horizontal

[1] A matter of detail is here ignored which has nothing to do with the main principle, and would only serve to perplex if I described it.

column by whose side 67– is marked, the entry 38 is found; this means that out of the 930 children 38 were born of mid-parentages of 69 and under 70 inches who also were 67 and under 68 inches in height. I found it hard at first to catch the full significance of the entries in the table, which had curious relations that were very interesting to investigate. Lines drawn through entries of the same value formed a series of concentric and similar ellipses. Their common centre lay at the intersection of the vertical and horizontal lines, that corresponded to $68\frac{1}{4}$ inches. Their axes were similarly inclined. The points where each ellipse in succession was touched by a horizontal tangent, lay in a straight line inclined to the vertical in the ratio of $\frac{2}{3}$; those where they were touched by a vertical tangent, lay in a straight line inclined to the horizontal in the ratio of $\frac{1}{3}$. These ratios confirm the values of average regression already obtained by a different method, of $\frac{2}{3}$ from mid-parent to offspring and of $\frac{1}{3}$ from offspring to mid-parent. These and other relations were evidently a subject for mathematical analysis and verification. They were all clearly dependent on three elementary data, supposing the law of frequency of error to be applicable throughout; these data being (1) the measure of racial variability, (2) that of co-family variability (counting the offspring of like mid-parentages as members of the same co-family), and (3) the average ratio of regression. I noted these values, and phrased the problem in abstract terms such as a competent mathematician could deal with, disentangled from all reference to heredity, and in that shape submitted it to Mr. J. Hamilton Dickson, of St. Peter's College, Cambridge. I asked him kindly to investigate for me the surface of frequency of error that would result from these three data, and the various particulars of its sections, one of which would form the ellipses to which I have alluded.

I may be permitted to say that I never felt such a glow of loyalty and respect towards the sovereignty and magnificent sway of mathematical analysis as when his answer reached me, confirming, by purely mathematical reasoning, my various and laborious statistical conclusions with far more minuteness than I had dared to hope, for the original data ran somewhat roughly, and I had to smooth them with tender caution. His calculation corrected my observed value of mid-parental regression from $\frac{1}{3}$ to $\frac{6}{17{\cdot}6}$, the relation between the major and minor axis of the ellipses was changed 3 per cent., their inclination was changed less than 2°. It is obvious, then, that the law of error holds throughout the investigation with sufficient precision to be of real service, and that the various results of my statistics are not casual determinations, but strictly interdependent.

In the lecture at the Royal Institution to which I have referred, I pointed out the remarkable way in which one generation was succeeded by another that proved to be its statistical counterpart. I there had to discuss the various agencies of the survival of the fittest, of relative fertility, and so forth; but the selection of human stature as the subject of investigation now enables me to get rid of all these complications and to discuss this very curious question under its simplest form. How is it, I ask, that in each successive generation there proves to be the same number of men per thousand, who range between any limits of stature we please to specify, although the tall men are rarely descended from equally tall parents, or the short men from equally short? How is the balance from other sources so nicely made up? The answer is that the process comprises two opposite sets of actions, one concentrative and the other dispersive, and of such a character that they necessarily neutralise one another, and fall into a state of stable equilibrium. By the first set, a system of scattered elements is replaced by another system which is less scattered; by the second set, each of these new elements becomes a centre whence a third system of elements are dispersed. The details are as follows:—In the first of these two stages, the units of the population group themselves, as it were by chance, into married couples, whence the mid-parentages are derived, and then by a regression of the values of the mid-parentages the true generants are derived. In the second stage each generant is a centre whence the offspring diverge. The stability of the balance between the opposed tendencies is due to the regression being proportionate to the deviation; it acts like a spring against a weight.

A simple equation connects the three data of race variability, of the ratio of regression, and of co-family variability, whence, if any two are given, the third may be found. My observations give separate measures of all three, and their values fit well into the equation, which is of the simple form—

$$v^2\frac{p^2}{2}+f^2=p^2,$$

where $v=\frac{2}{3}, p=1{\cdot}7, f=1{\cdot}5$.

It will therefore be understood that a complete table of mid-parental and filial heights may be calculated from two simple numbers.

It will be gathered from what has been said, that a mid-parental deviate of one unit implies a mid-grandparental deviate of $\frac{1}{3}$, a mid-ancestral unit in the next generation of $\frac{1}{9}$, and so on. I reckon from these and other data, by methods that I cannot stop to explain, that the heritage derived on an average from the mid-parental deviate, independently of what it may imply or of what may be known concerning the previous ancestry, is only $\frac{1}{2}$. Consequently, that similarly derived from a single parent is only $\frac{1}{4}$, and that from a single grandparent is only $\frac{1}{16}$.

The most elementary data upon which a complete table of mid-parental and filial heights admits of being constructed, are (1) the ratio between the mid-parental and the rest of the ancestral influences, and (2) the measure of the co-family variability.

I cannot now pursue the numerous branches that spring from the data I have given, as from a root. I will not speak of the continued domination of one type over others, nor of the persistency of unimportant characteristics, nor of the inheritance of disease, which is complicated in many cases by the requisite concurrence of two separate heritages, the one of a susceptible constitution, the other of the germs of the disease. Still less can I enter upon the subject of fraternal characteristics, which I have also worked out. It will suffice for the present to have shown some of the more important conditions associated with the idea of race, and how the vague word type may be defined by peculiarities in hereditary transmission, at all events when that word is applied to any single quality, such as stature. To include those numerous qualities that are not strictly measurable, we must omit reference to number and proportion, and frame the definition thus:—'The type is an ideal form towards which the children of those who deviate from it tend to regress.'

The stability of a type would, I presume, be measured by the strength of its tendency to regress; thus a mean regression from 1 in the mid-parents to $\frac{2}{3}$ in the offspring would indicate only half as much stability as if it had been to $\frac{1}{3}$.

The mean regression in stature of a population is easily ascertained, but I do not see much use in knowing it. It has already been stated that half the population vary less than 1·7 inch from mediocrity, this being what is technically known as the 'probable' deviation. The mean deviation is, by a well-known theory, 1·18 times that of the probable deviation, therefore in this case it is 1·9 inch. The mean loss through regression is $\frac{1}{3}$ of that amount, or a little more than 0·6 inch. That is to say, taking one child with another, the mean amount by which they fall short of their mid-parental peculiarity of stature is rather more than six-tenths of an inch.

With respect to these and the other numerical estimates, I wish emphatically to say that I offer them only as being serviceably approximate, though they are mutually consistent, and with the desire that they may be reinvestigated by the help of more abundant and much more accurate measurements than those I have had at command. There are many simple and interesting relations to which I am still unable to assign numerical values for lack of adequate material, such as that to which I referred some time back, of the superior influence of the father over the mother on the stature of their sons and daughters.

The limits of deviation beyond which there is no regression, but a new condition of equilibrium is entered into, and a new type comes into existence, have still to be explored. Let us consider how much we can infer from undisputed facts of heredity regarding the conditions amid which any form of stable equilibrium such as is implied by the word type must be established, or might be disestablished

and superseded by another. In doing so I will follow cautiously along the same path by which Darwin started to construct his provisional theory of pangenesis; but it is not in the least necessary to go so far as that theory or to entangle ourselves in any questioned hypothesis.

There can be no doubt that heredity proceeds to a considerable extent, perhaps principally, in a piecemeal or piebald fashion, causing the person of the child to be to that extent a mosaic of independent ancestral heritages, one part coming with more or less variation from this progenitor, and another from that. To express this aspect of inheritance, where particle proceeds from particle, we may conveniently describe it as 'particulate.'

So far as the transmission of any feature may be regarded as an example of particulate inheritance, so far (it seems little more than a truism to assert) the element from which that feature was developed must have been particulate also. Therefore, wherever a feature in a child was not personally possessed by either parent, but transmitted through one of them from a more distant progenitor, the element whence that feature was developed must have existed in a particulate, though impersonal and latent form, in the body of the parent. The total heritage of that parent will have included a greater variety of material than was utilised in the formation of his own personal structure. Only a portion of it became developed; the survival of at least a small part of the remainder is proved, and that of a larger part may be inferred by his transmitting it to the person of his child. Therefore the organised structure of each individual should be viewed as the fulfilment of only one out of an indefinite number of mutually exclusive possibilities. It is the development of a single sample drawn out of a group of elements. The conditions under which each element in the sample became selected are, of course, unknown, but it is reasonable to expect they would fall under one or other of the following agencies: first, self-selection, where each element selects its most suitable neighbour, as in the theory of pangenesis; secondly, general co-ordination, or the influence exerted on each element by many or all of the remaining ones, whether in its immediate neighbourhood or not; finally, a group of diverse agencies, alike only in the fact that they are not uniformly helpful or harmful, that they influence with no constant purpose—in philosophical language, that they are not teleological; in popular language, that they are accidents or chances. Their inclusion renders it impossible to predict the peculiarities of individual children, though it does not prevent the prediction of average results. We now see something of the general character of the conditions amid which the stable equilibrium that characterises each race must subsist.

Political analogies of stability and change of type abound, and are useful to fix the ideas, as I pointed out some years ago. Let us take that which is afforded by the government of a colony which has become independent. The individual colonists rank as particulate representatives of families or other groups in the parent country. The organised colonial government ranks as the personality of the colony, being its mouthpiece and executive. The government is evolved amid political strife, one element prevailing here and another there. The prominent victors band themselves into the nucleus of a party, additions to their number and revisions of it ensue, until a body of men are associated capable of conducting a completely organised administration. The kinship between the form of government of the colony and that of the parent state is far from direct, and resembles in a general way that which I conceive to subsist between the child and his mid-parentage. We should expect to find many points of resemblance between the two, and many instances of great dissimilarity, for our political analogy teaches us only too well on what slight accidents the character of the government may depend when parties are nearly balanced.

The appearance of a new and useful family peculiarity is a boon to breeders, who by selection in mating gradually reduce the preponderance of those ancestral elements that endanger reversion. The appearance of a new type is due to causes that lie beyond our reach, so we ought to welcome every useful one as a happy chance, and do our best to domicile and perpetuate it. When heredity shall have become much better and more generally understood than now, I can believe that

we shall look upon a neglect to conserve any valuable form of family type as a wrongful waste of opportunity. The appearance of each new natural peculiarity is a faltering step in the upward journey of evolution, over which, in outward appearance, the whole living world is blindly blundering and stumbling, but whose general direction man has the intelligence dimly to discern, and whose progress he has power to facilitate.

FRIDAY, SEPTEMBER 11.

The following Papers were read:—

1. *Insular Greek Customs.* *By* J. THEODORE BENT.

Reasons why the islands of the Ægean Sea have retained more ancient customs than the mainland: (*a*) from not being overrun by barbarian hordes, (*b*) not blended with Italian rulers, (*c*) leniently treated by Turks.

The customs concerning birth and childhood compared with ancient ones; fate-telling; deleterious influence of Nereids on children; the Nereids compared with ancient myths. The customs concerning death; the poetry of death-wails; the belief in Charon and Hades existing still; the freight-money for the ferryman of the Styx. Instances of burial in the islands. The feasts for the dead; belief in vampires; and other points which can be traced to a remote antiquity.

Love of a modern Greek for personifying the mysterious; a modern Erinnys; the views of an islander on the sun; the month of March.

Parallel cases from industrial life between ancient and modern times; the feast of Bacchus at Seriphos; Dionysos on Naxos; the drunken St. George on Paros; resinated wine.

Some instances from agricultural life of a like nature. Ceremony before the sowing of seed; skins for grain; granaries in the ground; ploughs, hoes, and other articles of agriculture; also names for animals.

2. *On the Working of the Ancient Monuments Act of* 1882. *By* General PITT-RIVERS, *F.R.S.*

3. *American Shell-work and its Affinities.* *By* Miss A. W. BUCKLAND.

In this paper the attention of anthropologists is called to some remarkable works in shell, recently discovered in mounds in various States of North America, as described by Mr. W. H. Holmes in a valuable contribution to the 'Proceedings of the Bureau of Ethnology,' Washington. These shell-works consist not only of beads of various forms and sizes, but also of celts, fish-hooks, clubs and other implements of war and the chase; bracelets, pins, crosses of various forms, and more particularly of masks and elaborately engraved gorgets, the ornamentation upon which seems to bear some religious or astronomical signification. Some of these forms are traced by Mr. Holmes to ancient Mexico, and Miss Buckland points out that not only are almost all the forms, both of implements and ornaments, to be found in islands of the Pacific, but also that some of the peculiar symbols engraved upon the ancient American gorgets re-appear slightly altered on shell gorgets in the Solomon and Admiralty Islands, and also on the great drum from Japan exhibited this year at South Kensington. From this, and from the record of a Peruvian vessel laden with merchandise having been met far out at sea by the Spanish navigators, it may be inferred that a commerce existed between the islands of the Pacific and the American continent prior to the Spanish Conquest, and that to this may be traced not only the resemblances in the shell ornaments

described, but also the similarity in the games and calendars of Mexico and Japan pointed out by Dr. Tylor, as well as some ethnical peculiarities observed by Mr. Moseley as existing in the Admiralty Islands.

4. *Note on the Redmen about Roraima.* *By* E. F. IM THURN.

After referring to his already published views as to the inter-relationship, origins, and classification of the various tribes of Redmen now in Guiana, the author dwelt specially on the places to be assigned in this classification to the Partamonas, Macoosis, and Arekoonas, the three tribes through whose territory he passed on his way to Roraima. Next he briefly detailed the route followed by him on that journey, with special reference to the anthropological facts noted by the way. This was followed by remarks on various special anthropological points; on the curious isolation of the one tribe from the other, and even in some cases of one part from another part of the same tribe; on certain survivals which he noticed of habits of the stone age, such as the persistent manufacture of stone implements and the retention, to some small extent, of the art of engraving pictures on rocks. Finally, a detailed account was given of certain games or dances which had been performed by the Macoosis for the amusement of the author, chiefly rudely dramatic representations of the doings of various animals and birds, together with a few representing impressive events which happen, but happen only rarely, in the lives of the players.

---

5. *A Game with a History.* *By* J. W. CROMBIE, *M.A.*

As children in their play generally imitate something they have observed to be done by their elders, and a game once introduced is handed down from generation to generation of children long after its original has ceased to exist, many innocent-looking children's games conceal strange records of past ages and pagan times; hence the importance of the study of this apparently frivolous subject is now fully recognised by anthropologists.

The game of 'Hop-Scotch' is one of great antiquity, having been known in England for more than two centuries, and is played all over Europe under different names. Signor Pitré's solar explanation of its origin appears improbable, for it would require the original number of divisions in the figure to have been twelve, whereas a considerable body of evidence can be adduced to show that it was seven.

It would seem more probable that the game at one time represented the progress of the soul from earth to heaven through various intermediate states, the name given to the last court being most frequently Paradise or an equivalent, such as Crown or Glory, while Purgatory, Limbo Rest, &c., occur as names of the other courts, which corresponds with the eschatological ideas prevalent in the early days of Christianity. Some such game existed prior to Christianity, and the author considers that it has been derived from several ancient games; possibly the strange myths of the labyrinths may have had something to do with 'Hop-Scotch,' and a variety of the game is played in England and France, upon a figure almost identical with that of a game described by Pliny as being played by the boys of his day.

The author believes that the early Christians adopted the general idea of the ancient game, but they not only converted it into an allegory of heaven, with Christian beliefs and Christian names, they Christianised the figure also; abandoning the heathen labyrinth they replaced it by the form of the Basilicon, the early Christian church, dividing it into seven parts, as they believed heaven to be divided, and placing Paradise, the inner sanctum of heaven, in the position of the altar, the inner sanctum of their earthly church.

6. *The Rule of the Road from an Anthropological point of view.* *By* Sir GEORGE CAMPBELL, *K.C.S.I.*

---

7. *On the Modes of Grinding and Drying Corn in old times.* *By* Miss JEANIE M. LAING.

In the lands of Tillyfour, in Aberdeenshire, are the ruins of an old hamlet, with straw kiln attached. Those kilns were used for drying corn before sending it to the mill. The kiln was conical in shape, joists called cabers were laid across, some distance from the ground. Above these were roughly hewn saplings called simmers. On top of these was spread straw, and on the straw was laid the corn. A fire was kindled on the ground, and the heat ascending, dried the corn. A stone called a sparker was placed above the fire, to catch the sparks. In spite of this precaution, the kiln sometimes took fire. When dry, the corn was put into a place called a 'dry corn bed.' When quite cool it was 'riddled' and sent to the mill. At an earlier period corn was ground between two millstones, with an iron rod by way of a handle. This primitive 'mill' was called a quern, and was generally turned by two females, as in Eastern lands. In later times querns were used for grinding malt. Straw kilns have not been in use in Aberdeenshire for nearly a century.

---

8. *The Flint-knappers' Art in Albania.* *By* A. J. EVANS.

The author exhibited some Albanian gun-flints and strike-a-lights, partially cased in ornamental lead sheaths studded with glass gems, and described the method now adopted by the Albanian flint-knappers for producing these highly finished implements. The flints were obtained from a range of hills distant about two hours from Joannina, and were mostly of tabular shape, scattered in profusion about the summit of a limestone plateau, but there were no signs of their having been used for manufacture in ancient times, nor have any flint implements of prehistoric date been found either in Epirus or Albania, though several polished stone axes of diorite and other materials have come to light. At present the chief site of flint-knapping industry is Valona and its neighbourhood, and in this case the flints are collected on the Acroceraunian mountains.

---

9. *The Discovery of Naukratis.* *By* W. M. FLINDERS PETRIE.

The work of the Egypt Exploration Fund which I have carried on in the first half of this year has brought to light the remains of the city of Naukratis, the great emporium of the archaic Greeks in Egypt. Though often sought for by travellers, no proof of its position had been obtained until I visited the mounds of Nebireh, about five miles from Teh el Barūd station on the Cairo and Alexandria Railway. No archæologist had seen the place before, and I only heard of it by inquiring of Arab dealers. Here I found a decree of the city of Naukratis, a coin of that city of an unknown type, and innumerable remains of the archaic period which agree closely with the historical accounts of the place.

Omitting all questions which relate only to art and architecture, we will briefly note the results which are of more general and scientific interest.

Naukratis was essentially a commercial and manufacturing centre of the Mediterranean trade during the early Greek period. The commerce is repeatedly mentioned by historians, and is amply proved by the great number of ancient weights of the different standards that are found: in six months my collection of weights rose to four times the whole number of Egyptian weights yet known and published, and double the number of Babylonian, while the Attic weights are about half the number yet known from Greece and other countries. The manufacturing importance of the place is shown by the various trades of which the remains were found. Ironworks flourished here as early as the middle of the sixth century B.C.—quantities of ore, of slag, and of finished tools of various kinds show this. Copper was also worked, the ore, slag, and finished objects remaining here. A silversmith's store of dumps of melted silver and early Greek coins yet unmelted was also found. Potteries existed on a large scale; the kilns

still remain, the thick strata of burnt earth thrown away in clearing them, and a great amount of pottery of a style not known elsewhere. Glazed ware was also made here, and large quantities of Greek imitations of Egyptian scarabæi and the moulds employed in making them; such scarabæi were exported to Greece, and are often found in early Greek tombs. Shell-working was also practised, and it is probably to Naukratis that we should attribute the carving of the Oriental *Tridacna* shells, usually attributed to the Phœnicians. Of the trade in later times, after Alexander, the immense quantity of amphora handles with names from Rhodes, Knidos, &c., are good witnesses.

On the history of Greek writing light is also obtained, and we see that as early as the beginning of the sixth century B.C. writing was almost universal on the hundreds of bowls and vases dedicated in the temples, fragments of more than two hundred such inscriptions having been found in clearing the rubbish-hole of the archaic temple of Apollo; among them one by the traitor Phanes which can be dated within a few years of 540 B.C. The majority, however, are earlier than this.

The history of Greek ornament is also illustrated, and we may trace the lotus pattern of Egypt, serving as the basis on which the Greeks developed their honeysuckle ornament with the aid of the Assyrian tree pattern.

In short, we see here the Greeks, with a versatile and highly plastic nature, rapidly developing their arts and manufactures upon the models of the old civilisation of Egypt.

Another, and very different, interest is afforded by the illustration of Egyptian ceremonial at the foundation of their great buildings. For the first time the series of ceremonial deposits has been found, and we see the models of the vases for the libations, the cups for offerings, and the sacrificial instruments of the ceremony; the models of the tools used on the building—the hoe, mortar-rake, adze, chisel, hatchet, trowel, and marking-pegs; the samples of all the materials—mud-brick, glazed pottery, agate, jasper, lapis-lazuli, turquoise, and obsidian; the metals—gold, silver, lead, copper, and iron; and the founder's name—Ptolemy II.—engraved on lapis-lazuli. A model mortar and pair of corn-rubbers accompanied these deposits, and may refer to some unknown ceremony, or to the purpose of the building.

The large collection of objects found will be distributed among public collections, the most important going to the British Museum.

SATURDAY, SEPTEMBER 12.

The Section did not meet.

MONDAY, SEPTEMBER 14.

The following Papers and Report were read:—

1. *On Ancient Tombs in the Greek Islands. By* J. THEODORE BENT.

The study of tombs in the Greek islands is conducive to a knowledge of ancient and forgotten lines of commerce. There are two periods in which the islands seem to have been especially used as depôts for trade:

1. The prehistoric period. Tombs at Antiparos; why this island is especially favourable for this study; nature of the tombs; the marble; obsidian pottery and jewellery finds; speculative remarks as to the date of this race which first peopled these islands.

2. The historic period. Rock-cut tombs on Karpathos; the commercial town of Bourgounta and its favourable situation for commerce; the various descriptions of rock-cut tombs to be found there, and the class of things found in them.

---

2. *A New Cave Man of Mentone.* *By* THOMAS WILSON.

In February 1884 there was discovered in one of the famous caverns at Mentone in the Alpes Maritimes, France, a skeleton of one of the ancient and original inhabitants, believed to have belonged to the paleolithic age. It is the purpose of this paper to give some of the details of the discovery, and offer some suggestions concerning the epoch to which the man belonged.

The caverns at Mentone are nine in number. They are nearly alike in their form, general character, and appearance. They are all in the same rock, with the same exposure or outlook, at the same level, belong to the same age, and were doubtless occupied at the same time. They form together a sort of prehistoric village, and their characteristics and evidence are not to be taken separately and isolated, but together and as a whole, making an aggregate testimony which gains momentum with each discovery.

The New Cave Man of Mentone.—Monsieur Rivière's discovery, and the name, 'l'homme de Menton,' by which it has been known, induces me to give this name to this discovery.

The excavations were made during the winter of 1883–4 by Monsieur Louis Julien, of Marseilles, and at his expense, aided by the advice of Monsieur Bonfils, Curator of the Museum at Mentone.

He employed four or five men continuously during the entire winter.

This cavern is marked on Monsieur Rivière's chart as No. 5, but is known in the neighbourhood as No. 4—'*la quatrième grotte.*'

It had been searched many times before, and about 9 or 10 feet in depth had been removed from the original surface, which, however, was plainly marked by a large piece of brèche which still adhered to the perpendicular side wall.

The formation of the floor of the cavern and the process of its filling up presented all the usual evidences of human occupation and industry: charcoal, burnt earth and ashes, hearthstones, split and broken bones of animals (estimated to the number of 15,000 pieces), flint instruments, chips, nuclei, &c., &c., were found in sufficient number, quantity, and distribution, to indicate an indefinitely long occupation.

No morsel of pottery was found, nor were any of the stone implements polished.

At the depth (from the original surface) of 8 mètres 40 centimètres was found the skeleton of this 'new cave man of Mentone.' He was laid on his back with his limbs extended, and had for funeral equipments three large chips of flint (*éclats de silex*) 6 or 7 inches long and 2½ inches broad, in the form of the largest scrapers, placed one on each shoulder, like epaulettes, and one on the brow. *It appeared to be an interment.*

This became more evident when it was found that the body was placed in a sort of natural vault or tomb, formed on one side by the wall of the cavern, and on the other by an immense block of stone with an overhanging edge, which reached to a line perpendicularly over the centre of the skeleton. This placing of the body required an excavation between these rocks of 3 or 4 feet in depth.

The skull was broken into sixty fragments by the pick of the workman; it was carefully taken up and put together by Monsieur Bonfils, and is now exposed in the Museum at Mentone. This was a fortunate accident, for while the rest of the skeleton was being exhumed a quarrel broke out as to the ownership, which ended in the theft and utter destruction of all that remained.

Observations.—Differences in the reports of the depth at which Monsieur Rivière's skeleton was found may be reconciled by suggesting the misapplication or misunderstanding of mètres and feet. He has reported the depth at 6 mètres and a fraction. It has been reported in English 6 feet and a fraction. Its

depth from the original floor was without much doubt about 6 mètres (20 or more feet).

Professor Boyd Dawkins believes these caverns to be of 'doubtful antiquity.' I suppose he means their occupation by man to be of doubtful antiquity. He asserts there is nothing to show that the earth has not been disturbed down to the layer at which the skeletons were found; and Monsieur Mortillet classes Monsieur Rivière's *l'homme de Menton* as neolithic, because of the interment and of the bone *poinçon* and shell beads found with him.

The new discovery dissipates all idea of disturbance, for while *disturbance* might exist for one or two, or even five or six feet, to the depth of twenty or thirty feet it would be impossible.

It must be conceded that the human industry, as manifested by the objects found in these caverns, indicates their occupation during the paleolithic age, for of the thousands found all bear the impress of that age, while none denote particularly the age of polished stone.

To say that the interment belongs to an occupation subsequent to that indicated by the implements found in the cavern, means an interment made by a subsequent race, and consequently made from the then surface or floor of the cavern. This would require a grave to be dug by the neolithic man with his fingers, his stone hatchet, or his deer-horn pick, to a depth of from 6 to 9 mètres, or 20 to 30 feet. This, in earth packed hard and solid, filled with sharp stones, flint chips and implements, and bone splinters, may be regarded as improbable, if not impossible.

It took Messieurs Rivière and Julien, with a full corps of trained and paid workmen, working under an overseer, and armed with all modern implements, steel picks and shovels, barrows, &c., from one to three months' steady work to arrive at the same depth.

That there was an interment would seem to be undoubted, but it was made from a reasonable depth, and was sufficient to serve the purposes of protection and safety of the body. A 'reasonable depth' say from three to eight feet for this purpose would seem to indicate the occupation and industry of that people to which the deceased in his lifetime belonged. This is clearly paleolithic, and not neolithic—is, in fact, the Madélienne époque of Monsieur de Mortillet, if not earlier, and approaching the Moustérienne.

The occupation of this country by prehistoric man would seem to be divided into three zones or belts:

1. On the border of the sea, by the paleolithic man. Possibly the glaciers prevented his occupation farther inland, or destroyed the evidence of it, if any existed.

2. On the heights, and inland for a few miles, by the neolithic man, where are to be found pottery, flint, and in some places bronze.

3. All that country farther inland and among the mountains, in which, as yet, none or very few prehistoric remains of any age have been found.

---

3. *Happaway Cavern, Torquay.* *By* WILLIAM PENGELLY, *F.R.S.*, *F.G.S.*

Happaway Cavern occupies the south-western slope of a *Devonian* limestone hill bounding the principal street of Torquay, and is about 200 feet above the sea. It was discovered in October 1862 by quarrymen breaking into it in the ordinary course of their work, and, at the request of the late Lord Haldon, the proprietor, the author undertook its exploration in June 1863, when he performed the manual labour with his own hands in order to eliminate all possibility of doubt respecting the genuineness, as well as the exact positions and associations, of such objects of interest as might be found.

The cavern, when completely emptied in 1866, proved to be about 46 feet long, from 10 to 15 feet broad, and 10 feet high. There was no stalagmitic floor, nor

any satisfactory indication that there ever had been one. The deposit was usually divisible into three zones:—

First, or uppermost.—Fine friable earth, of light chocolate colour, rather dry, containing bones and bits of charred wood, but very few stones. Extending from the surface to about six inches below it.

Second.—Moist tenacious earth, of dark colour, containing bones and bits of charred wood, stones lying at all angles, and commonly angular but occasionally rounded. From 6 to 24 inches below the surface.

Third, or lowermost.—Coarse earth, of somewhat bright red, and rather sandy, differing from the higher zones by the presence of larger and more numerous stones, with occasional blocks of limestone and pieces of stalagmite, while charred wood and bones were less plentiful.

The objects of interest met with were a few marine shells, numerous terrestrial shells, one joint of the vertebral column of a fish, a few bones of birds, bones of badger (very numerous), deer, fox, pig, sheep, hare, rabbit, small rodents, bat, two teeth of bear, parts of two teeth of rhinoceros, one tooth of hyæna, a lower human jaw, and parts of two human skulls.

There were also a few human industrial remains, including charred wood, an infra-human skull artificially divided, about fifty flint flakes and chips, and two groups of miscellaneous objects taken in by rats or other small animals, and including scraps of paper—many of them printed, bits of cord, very fine wood-shavings, and pieces of ribbon.

---

4. *On the Human Remains found in Happaway Cavern, Torquay. By* J. G. Garson, *M.D.*

Dr. Garson stated that the bones submitted to him by Mr. Pengelly from Happaway Cavern consisted of the greater part of a cranium, a mandible, and some fragments of the cranium of a child. The bones afforded no indication of being of great age. The cranium was mesaticephalic, and was distinctly different from either the Long or Round Barrow types, indeed, it presented mixed characters, and was such as might be found in any modern graveyard.

---

5. *On Three Stone Circles in Cumberland, with some further observations on the relation of Stone Circles to adjacent hills and outlying stones. By* A. L. Lewis, *M.A.I.*

The author referred to a paper read by him at the York meeting, in which he had shown that in eighteen circles in England and Wales there was a marked preponderance of outlying stones or prominent hills towards the N.E., and that the line S.W. to N.E. was specially characteristic of circles, in opposition to the line N.W. to S.E., which was most usual in stone chambers. He then described three circles in Cumberland, bringing forward evidence as to some outlying stones not, so far as he knew, previously noticed, and showed that these circles conformed to the rule already laid down, and that, whereas the Egyptians and the Babylonians followed different rules of orientation, the circle builders followed the Babylonians rather than the Egyptians—a fact which might ultimately be found to have some anthropological importance. After mentioning various facts bearing upon the subject generally, and giving a notable instance of a connection between the temple of another religion and a hill at some distance from it, Mr. Lewis said that in the relation between stone circles and adjacent hills and outlying stones suggestions might be found not only of sun worship, but of mountain worship and phallic worship, not all of which would, however, necessarily have been obvious to every worshipper in the circles.

---

6. *The Archæological Importance of ancient British Lake-dwellings and their relation to analogous remains in Europe.*[1] *By* R. Munro, *M.A., M.D.*

Dr. Munro commences by giving a short introductory notice of the discovery and investigation of the crannogs of Ireland and the lake-dwellings of Central Europe. He then gives a *résumé* of the more recent explorations made among the crannogs of Scotland and the remarkable objects recovered from them. From a comparative examination of these relics with other collateral antiquities of the Celts, he arrives at the conclusion that the lake-dwellings of Scotland were essentially the product of Celtic genius, that they were constructed for defensive purposes, and that those in the south-west parts of the country attained their greatest development in post-Roman times, after Roman protection was withdrawn from the provincial inhabitants, and they were left single-handed to contend against the Angles on the east and the Picts and Scots on the north. Having established the Celtic origin of the crannogs of Ireland and Scotland, Dr. Munro proceeds to inquire if there is any ancestral relationship between them and the lake-dwellings of Central Europe. Taking into account the recent discovery of lacustrine abodes in the Holderness, and the few previous records of their existence in Wales and other parts of England, together with the statement of Cæsar that the Britons were in the habit of making use of wooden piles and marshes in their defensive works, he thinks that such indications are not merely solitary instances, but the outliers of a widely distributed custom which prevailed in the southern parts of Britain at an earlier date than that assigned to the crannogs of Scotland. Hence he suggests the theory that the British Celts were an offshoot of the founders of the Swiss lake-dwellings, who emigrated into Britain when these lacustrine abodes were in full vogue, and so retained a knowledge of the custom long after it had fallen into desuetude in Europe. On this hypothesis it would follow that subsequent immigrants into Britain, such as the Belgæ, Angles, &c., being no longer acquainted with the subject, would cultivate new and perhaps improved methods of defensive warfare; whilst the first Celtic invaders, still retaining their primary notions of civilisation, when obliged to act on the defensive would naturally have recourse to their inherited system of protection.

In support of this hypothesis the author points out that the geographical distribution of lake-dwellings, so far as they are known in Europe, closely corresponds with the area formerly occupied by the Celts; that no lake-dwellings have been yet found either in the northern or southern parts of Europe, though the topographical and hydrographical conditions of these regions are not unfavourable for such structures; that the *fascine* dwellings in Europe were identical in structure with the crannogs; and that, though the pile-dwellings were not largely used in the British Isles, the principles on which they were built were not unknown, their disuse being due to topographical and other considerations. Finally, he argues that the wideness in the chronological gap which is supposed to separate the crannogs from the lake-dwellings of Europe is more apparent than real, as the latter existed during the Roman occupation of Gaul, and in one instance at least the custom survived to about the tenth century.

---

7. *The Stone Circles in Aberdeenshire, with special reference to those in the more Lowland parts of the County, their Extent and Arrangement, singly or in groups, with General Observations. By the* Rev. James Peter, *F.S.A. Scot.*

The main object in this paper is to draw attention to and put on record the existence of so many interesting remains of a remote antiquity in this part of Scotland, and chronicle any information which may be deemed important as throwing light on a subject admittedly dark and obscure.

[1] See by the author, *Ancient Scottish Lake Dwellings (or Crannogs)*, with a supplementary chapter on Lake Dwellings in England; Edinburgh, David Douglas. Also *Journal of Anthropological Institute* for 1886.

The stone circles of Aberdeenshire, over thirty in all extant, are spread across the county, but the author's observations are confined mainly to the group in the parish of Deer.

They extend over a wide area, appearing now singly, now in groups. For long there would appear to have been no disturbing cause affecting their removal, but since the impulse given to agriculture some sixty to seventy years ago, this destruction has been lamentably frequent.

As to the arrangement: Putting aside the isolated circles, it may be stated that they arrange themselves generally in a group of three, as in the case of Newton, Lonmay, &c. The great exception to this is the large group of circles in the parish of Deer, or Old Deer, as it is now generally called, comprising an area of 25,711 acres imperial, or about 40 square miles. This group consists of seven circles more or less complete. It occupies the centre of the large district of Buchan, or north-eastern division of Aberdeenshire. The circles, including those still subsisting in part as well as those now extinct, stretch in a line almost due north and south, ten miles in length, from Strichen on the north border of the parish, to the hill of Skelmuir on the south. They are all of the same character, with a single exception, and placed on the summit of one or other of the secondary knolls, not generally exceeding 350 feet, which diversify the surface of the parish. A certain regularity attaches to their position, indicating design on the part of those who erected them, while an examination of them singly, in reference to their contiguity, proves that the chain was so constructed that each link was visible from the nearest, and also that thus by a zigzag glance communication was established from one to the other. This assertion has been verified by actual and careful observation.

As to the measurements of the circles generally: Taking seventeen of the most complete in the county, it is found the average diameter is 54 feet, number of stones that composed the circle 12, average height of the largest individual stones 7 feet, distance between the monoliths $13\frac{1}{2}$ feet. In the case of all save three of the circles the altar-stone is on the south meridian, but in the exceptions it faces the N.E. Of the extant and comparatively complete circles, the one at Aikybrae or Parkhouse, and the other at Strichen, have a similar arrangement and character. Both altar-stones have their top flattened with a slope towards the east, and are fixed in position by two stones in the shape of wedges on either side, but not opposite, having an opening underneath sufficient to admit of a thong or cord being passed. The altar-stone in the Parkhouse one is specially mentioned by Colonel Forbes Leslie, and its size given as length $14\frac{1}{2}$ feet, breadth $5\frac{1}{2}$, and depth $4\frac{1}{2}$ feet, its gross weight exceeding 21 tons. A third circle, that known as the Loudon-wood circle, differs from the Parkhouse one, $2\frac{1}{2}$ miles distant, in the matter of the altar-stone and side altar-stones, though not in the enclosing stones. The altar-stone is not flat but ridgy, while each of the side-stones seen in profile towards it presents a very perfect crescent or curve, which, extended on both ends until they met, would form a pretty perfect circle with its centre in the middle of the altar-stone. It is evident that this was no haphazard arrangement, but one of purpose, be that purpose what it may. There is one other circle in the group so different from the others that it demands special notice, viz., the White Cow circle. Here there is no recumbent or altar-stone, but the circle is formed of small irregular stones placed close together and in most cases half buried in heath. In the centre, or rather on the corner of the N.E. quadrant, if we divide the circle by lines from N. to S. and E. to W. passing through the centre, is placed a dolmen, the table stone of which, once supported by five stones, one on the E., two on the N., with two on the S., has been lowered at the open end by the forcible removal of one of its northern supports. As the direction of the table-stone seemed not to be towards any cardinal point of the compass, I resolved to ascertain its actual position, and careful observation has brought out the important fact that a line drawn along the centre lengthwise from W. to E., and projected to the horizon, would strike it as near as may be at 47° north of E., or at the rising of the sun on Midsummer Day. The latitude of Deer being 57° 34′ N., sunrise on Midsummer Day would occur at about 47° 41′ north of E.

The multiplication of these stone circles, and specially in the north-eastern part

of Aberdeenshire, as at Deer, may be assumed as pointing to the existence of a considerable population in early times, and if colonisation came from the east, and possibly Scandinavia, the most easterly point of Scotland would naturally be one of the earliest objective points. Leaving the inhospitable shore, where now stands the flourishing port of Peterhead, the new comers would move on up the valley of the Ugie in search of shelter, where they would find it in a district protected from the cold north by moderately high rounded hills, clothed as tradition asserts, and the mosses prove, by the friendly oak and hazel. That a large population must at an early period have here existed is attested by the numerous cairns and tumuli that extend on either side the river towards the west, while scarcely a height but retains the remains of some rath or circle within which dwelt the inhabitants with the Maormohr or chief.

---

8. *Stone Circles in Aberdeenshire.* *By* JOHN MILNE, *M.A.*

Biffie circle in Deer is a good example. It is 50 feet in diameter and is made up of one large horizontal block and ten erect pillars, some now fallen, connected by a low wall. The largest stones, as usual in such circles, are placed on the south side and the smaller on the north. The best stones at command were always taken, but any stone, though not a foot in height, served when better could not be got; they are mere place-markers. What would these stones tell us if we could understand their language, for they are evidently speaking to us? They were not places for defence. Some are on hill-tops, but others on hill-sides commanded by higher ground. Nor for worship; they are numerous in some places and not found at all in other places; no sanctity attached to them for long. One may be seen encroaching on another whose pillars are still standing. Probably they were places of sepulture prepared by kings and chiefs during their lifetime, to be occupied by them after death. One circle had inside the outer row of pillars a large closed chamber filled with gravel, and on the centre of the floor was an urn. On the death of the builder his ashes had been carried into the chamber by a low covered way, and then gravel had been poured in by an aperture at the top. It is not to be wondered at that urns and bones are seldom found in them. Ancient graves in Aberdeenshire are usually shallow, often not a foot deep, merely a small hole into which the ashes of a body burned beside it had been put, with a few small stones for a covering. The graves in the circles had probably been rifled long ago, and had also been subsequently examined repeatedly in search of valuables. The round tower of Mousa, in Shetland, had been perhaps a tomb; it is not suited for defence. The great group of circles in Nairn had probably been erected by the line of Pictish kings who were reigning at Inverness about the time of Columba's visit, and the circles in Deer may with much probability be regarded as the tombs of the mormaers of Buchan, mentioned in the Book of Deer. There is a certain similarity between the Scottish and English circles. Like the northern circles, Stonehenge has the horizontal stone on the south, and round it stood the trilithons, the loftiest to the south.

9. *Notes on a recent Antiquarian Find in Aberdeenshire.* *By* Dr. F. MAITLAND MOIR.

---

10. *The Picts and Præ-Celtic Britain.* *By* HYDE CLARKE.

In preparing a paper for Aberdeen, Mr. Clarke, being desirous of its having a local bearing, chose the question of the Picts. This he proposed to deal with in reference to the inquiries of himself and others as to the præ-Celtic inhabitants of Britain. In continuing his own investigations, he set aside the distinct Basque hypothesis, and treated the influences historically and topographically traceable as Iberian in a wider sense. The Picts have presented a difficult problem, the materials relating to which have been most ably dealt with by Dr. Skene, in his edition of the Chronicles of the Picts. His ultimate conclusion was that the Picts

were, in all probability, non-Celtic, and at the same conviction Professor Rhŷs has arrived, and also at the opinion they were Turanians. Dr. Skene found that the Pictish kings did not succeed from father to son, confirming the statement of Beda that there was a female succession. The male succession begins with Malcolm Canmore. Dr. Skene found that out of forty-two names of Pictish kings a score were of the types of Talarghan, Talan, Taran, &c.; about a quarter Brude, and about a quarter Drust. As these are non-Celtic there is a ground to seek for them in Iberian names, as in the names of the rivers, cities, and southern British kings. The names of kings have to be sought in the heroic epoch precedent to the adoption of Hellenic names. They are to be found in the forms Telegonus, Telkhines, Telkhis, &c., being of the model of Tarkon and Tarkondimotos. So Brude is found under similar circumstances as Proteus, Prœtus, &c., and Drust as Adrastus, &c. In the heroic epoch these three names are found in connection. Brude is the same name as the Brutus, King of Britain, of Geoffrey of Monmouth, whose fables sometimes transmit traditions and sometimes by chance afford parallels to other traditions. Dr. Skene, Professor Rhŷs, and Mr. Grant Allen have pointed out the peculiar relations of the Picts to the Cymric Britons, their late acceptance of Christianity, their retention of a peculiar language, and their bearing towards the Danish invaders. These and other circumstances are explained by considering the Picts as representing the Iberian populations of Britannia and Hibernia, closely pressed by the Celtic invasion and making their last stand in Caledonia among kinsmen. The Picts were as much reviled by the British historians, Gildas and Nennius, as were the Saxons. The Pictish language dying out left a readier opening for the spread of English in Caledonia, the adoption of which was resisted in Wales and in Cornwall. Dr. Skene stated that the husbands of the Pictish mothers of the kings must in some cases have been foreigners, and he traced the case of Eanfrid, son of a king of Northumbria. The advance of knowledge shows us in surviving institutions the nature of exogamy once more widely spread. Under this institution a man or woman cannot marry into the tribe, but into another tribe, while the offspring are held to belong to the tribe of the mother and not of the father. In various historical examples this female succession or matriarchy has been disturbed by male succession, and constantly by Aryan influence. Thus the real explanation of the instance of Malcolm Canmore is that he established the male succession. Mr. Hyde Clarke advocated the collection and preservation of local non-Celtic names in title-deeds and records as a means of affording philological materials.

11. *Report of the Committee for investigating and publishing reports on the physical characters, languages, and industrial and social condition of the North-western Tribes of the Dominion of Canada.*—See Reports, p. 696.

TUESDAY, SEPTEMBER 15.

The following Papers were read:—

1. *Notes on the opening of a Cist, in the Parish of Leslie, Aberdeenshire. By the* Rev. JOHN RUSSELL, *M.A.*

The parish of Leslie is intersected by the Gadie. It seems to have had a large population at a very early date. It is rich in prehistoric remains, though in the course of agricultural improvements many have disappeared. In the locality are remains of stone circles. Flint spear and arrow heads, stone celts and hammers, whorls and scrapers, have been found in abundance.

The cist to which I refer was found by a farmer in New Leslie when digging sand in a corner of a field. On communicating with me, we examined the place but did not open it up until an opportunity was given to the public to be present.

The cist was on the slope of a ridge lying to the south. The upper part was about three feet below the surface. The sides and cover were of stone slabs of the kind called Correen stone, and had the interstices filled in carefully with fine white clay like putty. This with the site, decomposed granite, had excluded air and moisture.

The contents were a skeleton of which the large bones were complete, and also the skull, which contained all the teeth regular but worn flat.

There was an earthenware urn ornamented, and below the urn two flint spear heads beautifully worked.

I infer from the cist and contents that there was then a belief in a future state.

(1) The act of burial shows this.

(2) The care shown in constructing the cist and its contents. With rude implements the grave had been scooped out, the stones of the sides and cover had been carried for about six miles.

(3) The skeleton lay east and west, with the head looking to the east.

(4) There was nothing inside the urn. It had probably been filled with food for the deceased.

(5) The weapons. These were to be with him in the happy hunting ground to which it was believed he had been translated.

---

2. *Notes on a Cist found at Parkhill, Dyce, in October* 1881. *By* W. Ferguson.

---

3. *On the Human Crania and other contents found in short stone Cists in Aberdeenshire. By* Professor J. Struthers, *M.D., LL.D.*

Professor Struthers described the leading features of the bones found in eight short stone cists in Aberdeenshire, exhibiting the bones and giving the conclusions which he arrived at as to the sex, age, and stature of the bodies interred in the cists. Most of the bodies were those of men of good stature. Professor Struthers referred specially to a large-sized urn found in a farm in the parish of Fyvie, and which had been sent by the Rev. Mr. Leslie. The urn had been found in a circular hole, measuring 4½ feet in diameter, which had been made in the ground, and a quantity of peat ashes indicated that cremation had taken place. The bottom on which the urn had been placed was coated over with clay to the depth of two inches, covered with small flat stones. The bottom of the cavity on which the urn rested was 2 feet 5 inches from the surface. The urn was made of clay, unglazed. The bones found in the urn were very much broken up.

---

4. *Notice of Human Bones found in* 1884 *in Balta Island, Shetland, by D. Edmonston, Esq. By* Professor J. Struthers, *M.D., LL.D.*

The paper stated that while Messrs. Ritchie and Downie, fish-curers, were erecting a fish-curing station in Balta Island, there was found a number of skeletons. The workmen first came upon one skeleton lying at full length, the bones of which were in perfect preservation. The bones were those of a man over six feet in height. Subsequently other twelve skeletons were laid bare, all complete except one. All the bones were of large size and were those of men. The bodies had not been enclosed in coffins, and they had not been interred with any degree of regularity. Some had been buried on their backs, others on their sides, and two of them face downwards. None of the bodies were found more than eighteen inches below the surface. Professor Struthers said that he had received the bones, which were at present to be seen in the gallery in connection with the Anatomical Museum. There was nothing particular about the skeletons. The bones were all quite fresh. Bones might be in sand hundreds of years, and remain fresh. The bones in question were those of strong men, adolescent and of middle age.

Dr. Struthers concluded by inviting the members to view these urns and bones, arranged in a gallery in one of the anatomical laboratories at Marischal College, and also a number of interesting skulls of various races of mankind, which he had placed there for the occasion. He also mentioned that Aberdeen University was now forming at King's College a museum of archæology, which they hoped would represent the prehistoric remains of man in the north-east of Scotland. As convener of the committee on the movement, he stated that they would be glad to receive all such specimens found in the district.

---

5. *Some important Points of Comparison between the Chimpanzee and Man. By* Professor D. J. Cunningham.

Professor Cunningham exhibited some plates of frozen sections of the chimpanzee, which brought out several important points of comparison between it and man.

---

6. *Abnormal and Arrested Development as an Indication of Evolutionary History. By* J. G. Garson, *M.D.*

Dr. Garson began by stating that, perhaps, the most fertile source of information regarding the history of man's evolution is derived from a study of his embryological development. Another source from which much valuable information regarding the early history of our own specialisation, and that of other animals, might be gleaned, is Teratology, which had for its domain the consideration of abnormal conditions of development. Many of the conditions included under this branch are of a pathological nature, and due to the effects of disease; others, however, are not—such, for example, as an abnormal and unusual production of normal structures and cases of arrested development. To a consideration of some conditions occurring under one or other of these categories he called attention. The examples which he had selected had come more especially under his own observation. Persons are occasionally found with abnormal development of hair on their bodies. The type mammal was an animal whose body was covered with hair. Under certain circumstances hair may more or less disappear, according to the conditions under which an animal lives. In man it is only feebly developed, except on the head; and in the cetacea or whales it has entirely disappeared, with the exception of a very few bristles near the mouth. Dr. Garson proceeded to explain how universal development of hair takes place in man. In ordinary cases the hair-growing apparatus in the embryo remains stationary, instead of keeping pace with the growth and development of the other organs of the body, with the result that no hairy covering such as is found in other mammals is present, but only short rudimentary hairs appear at intervals. But in some exceptional cases this stationary condition of the hair follicles does not occur, and they go on actively developing with the rest of the body, with the result that a hairy covering is produced. The hairless condition now normal in man has evidently been gradually acquired through a long period of time, as such a change could not take place rapidly and become such a stable condition as it is found to be otherwise.

Abnormal development of fingers occurs sometimes in man, but must be classed entirely apart from such forms of abnormality as had been considered in the hair-growth. Supernumerary digits occurring in animals with a less number of digits than five indicated evolutionary changes in some cases, but in others were due to the same cause as their appearance in man.

In arrested development the abnormal organ or portion of the body, instead of going through the various stages it usually does till it arrives at the condition it normally assumed in the group of animals in which it occurs, stops short at one or other stages. The stage at which it stops may correspond to that which is normal in a lower grade of animal life, and so gives direct evidence that the higher forms of animal life, such as man, pass through and beyond the stages at which the lower stop. It must not be forgotten also that in some respects an

animal of a lower grade may possess specialisations in some structures or organs of a higher ground than animals much higher in the scale of life. Cases of arrested development give us a clue as to how these specialisations occur. It was explained how cases of median harelip in the human subject may correspond to a normal condition in the cat and rabbit, and how abnormal conditions of the nose sometimes occurring in man, indicate how the modification in the nasal organ of the elephant was produced.

---

7. *The Symbol Pillars abounding in Central Aberdeenshire. By the* Rev. JOHN DAVIDSON, *D.D.*

The following are the principal points referred to in this paper:—

Peculiar symbols, incised chiefly upon unhewn monoliths, found over the north-east parts of Scotland, but mostly in the centre valley of Aberdeenshire.

Similar prevalence of stone circles. These traceable also along the supposed routes of Celtic migration from Asia.

Relative antiquity of symbol pillars and cross-bearing slabs in the same district of Scotland.

Coincidence in locality of symbol pillars and such inscriptions with ancient Pictish kingdom.

Symbol sculptures not the work of Christian times, or of the Romans, or of the Scots who succeeded the Pictish dynasty.

Certain particulars associating the sculptures with the Pictish people and with eastern Celts.

Hypotheses as to origin and meaning of symbols. Early and important inhabitation of Central Aberdeenshire. Pictish connection.

Remarkable finds in the district.

---

8. *Notes on some of the Bantu Tribes living round Lake Nyasa in Eastern Central Africa. By* Dr. ROBERT LAWS.

Lake Nyasa is 350 miles long, varying in breadth from 16 to 60 miles, with 15 different tribes living round it, each speaking a separate language. Best known of these are:—At the north end, the Anachusa coming from a point farther northward. Round Bandawe are the Atonga, while at Kotakota on the west, and Losewa and Makanjira on the east side of the Lake, are the Swahili and Arabs. To the west of Cape Maclear are Awisa from Lake Bangweolo. Yao, from the sources of the Rovuma, conquered the Anyanja, and are masters of the south part of Nyasa, and the hills to the east of the Upper Chiri River. The Anyanja or lake people lived on the lake shore, and apparently extended far to the north. On the highlands west of Lake Nyasa are the Angoni or Maviti. They came from the banks of the River Umsunduso, and crossing the River Zambezi in 1836, conquered many tribes, broke up into sections, and settled in different places.

The natives are generally well developed physically, but vigour of body and mind is affected by climate and food. Prognathism is not very marked. Umbilical hernia is very common at some places. In walking the natives do not turn out their toes, and the second toe is always longer than the great toe. The reputed keenness of vision and acuteness of hearing of uncivilised tribes is due rather to the contrast between the training of the native and the traveller than to any difference of the organs. In endemic diseases the European constitution resists the onset of the disease longer, but suffers more acutely from such than the native.

The natives depend chiefly on agriculture for subsistence. No traces of a stone age have been found, but there are lake dwellings to be seen. There are iron mines in several places, and copper also is found. The smelting furnaces for iron of the Atembuka are 15 feet high, with eight blast pipes, and in section similar to those employed at home. Canoes consist of hollowed trees. Fishing nets, made of ntingo bark and bwarze fibre, are of different sorts. Hunting is common in certain districts. Dogs are used in following rabbits; nets, pitfalls, spears and guns for larger game.

Clothes are made of the inner bark of a tree, but some wear skins. The manufacture of cotton cloth, on the Chiri, is giving way to English calico. The Anachusa use a mordant in dyeing.

The architecture of the houses is simple. All houses are round, but the different tribes construct them differently. Pottery is the work of the women, and is done by hand. Some of these vessels are very neat. Grain is pounded in wooden mortars, and ground by rubbing between two stones. Their most common dish is a stiff porridge.

Natives measure time by days, lunar months, and years; they thrust a stick into the earth and also use the middle finger of the hand to form rude sundials. Their knowledge of the facts of natural history is surprisingly accurate, and they have names for all the things they see. Their practice of medicine is more the use of charms, but they know some plants with powerful properties. Their ordeal poison bark, called mwave, is the *Erythrophlœum guineense*, which if not vomited causes death. Their most deadly poison for arrows is the gall of the crocodile. They use several emmenagogues, and know to pierce the membranes to produce abortion. Obstetric practice is in the hands of old women, but if nature fails, patients are left to die; yet the Anachusa know how to rectify the malpresentation of a calf. In surgery they know how to set fractures with splints of reeds, reduce dislocations, and bleed by cupping, and by opening the temporal artery. Lacerated wounds they dress with charcoal and oil; an indolent ulcer is treated by scrubbing the surface with the core of a mealie cob.

Slavery is common, but infanticide is not practised. Polygamy is the general custom. Among the Atonga, a girl is often betrothed before she is born. The Angoni give cattle to a father-in-law on marriage, and among them immorality is punished by death.

Land nominally belongs to a chief, but really to a tribe; occupation being the only proof of personal or family possession. For the repression of crime, murder is punishable by death, but blood-money is often accepted. A person attempting to steal, if it is dark, may be killed, but if recognisable must not be so treated. The ordeals in common use are by boiling water and the mwave poison. The government is patriarchal. The plebs have no voice in it; but among the Angoni they use the songs sung at their martial dances to express their political feeling.

All the tribes believe in the immortality of the soul, some in its transmigration. Among the Angoni ancestral worship is the only religious conception; but among the Anyanja there is also the idea of a deity, and among the Anachusa the idea of a Supreme Good and an Evil Spirit. Their folk-lore contains the common Bantu story of the origin of death, and among the Angoni there is a legend of a wooden Tower of Babel.

The languages all belong to the Bantu family. The characteristic of this is the principle of euphonic or alliteral concord, by which the euphonic letter or syllable of the noun recurs in the depending parts of speech in the sentence, thus:—My big cup fell and is broken—*Tshi*ko *tshatshi*kuru *tsha*nga *tshi*nagwa ndimo *tshi*naswedwa, where the concord is marked by italics. The verb is very elaborate, the simple form having a positive and a negative conjugation of the active and passive voices. Secondary and tertiary derivative forms can be made from the simple form, and each of these passes through all the inflections of the simple form. A complete paradigm of the Chinyanja verb would show more than 27,000 different examples of the third person singular. What is the meaning of the word 'savage'?

10. *A brief Account of the Nicobar Islanders, with special reference to the Inland Tribe of Great Nicobar. By* E. H. Man.

In the interior of Great Nicobar there is a wild race, styling themselves 'Shab Dawá,' of whom as yet little information has been obtainable; they are distinct

from the inhabitants of the other islands and of the villages on their own seaboard, who are of Malay origin, and by whom they are called 'Shom Peṅ' ('Shom' denoting 'tribe,' and 'Peṅ' being the tribal designation).

It appears certain that they are the descendants of a very ancient aboriginal population of Mongolian origin. The first mention that we find of them is from the pen of Pastor Rosen, a Danish missionary, who, while resident at the Nicobar Islands between the years 1831–34, spoke of them, from hearsay, as in much the same degraded condition as we find them at the present day. He said that 'they wear no clothes, possess no houses, live like animals in the depths of the forests, and shun the sight of men, never leaving their lairs except to search for food, which they sometimes steal from such of the coast huts as are temporarily vacated, or occupied only by a few aged or infirm folk whom they are able to surprise or overpower.'

In 1876 and 1881 a few members of this tribe living near the north-east of Great Nicobar were seen by the late Mr. de Röepstorff, who in the latter year accompanied Colonel T. Cadell, V.C., Chief Commissioner of the Andamans and Nicobars, in a visit to their encampments. During the last eighteen months Mr. E. H. Man, while in charge of the Nicobar Islands, has paid six visits to Great Nicobar, on four of which he succeeded in seeing and photographing parties of this tribe, both near Ganges Harbour and on the west coast.

On the first of these occasions (viz., February 1884) two youths, aged about eighteen and fourteen years respectively, were persuaded to leave their friends for seven days, at the end of which they were conveyed back from Nancowry in the settlement steamer. During their visit to Mr. Man they proved themselves tractable and timid, and submitted with a good grace to ablutions which were found very necessary. Although this is the first recorded instance of a Peṅ having ventured from his savage haunts, these lads exhibited the Oriental characteristic absence of wonderment at all the novel surroundings and tokens of civilisation in the Government settlement. They were fair specimens of their race, the members of which are found to be usually well nourished, of good physique, and, while young, favoured with pleasant features. The height of the males appears to range between 5 feet 2 inches and 5 feet 8 inches; their skin is fairer than that of the generality of the coast people, who, on their part, are less dark than the Malay; the hands and feet seem to be decidedly large, and bear evidence of the rough work of their daily lives; the hair, which is straight, is commonly worn uncut and unkempt, and, as habits of cleanliness are manifestly foreign to their nature, its condition can better be imagined than described.

As a result of their friendly intercourse in recent years with the coast people, they have acquired the habit, so universally practised among the latter, of chewing the betel-nut (*Chavica betle*) with or without quicklime, and are consequently beginning to be similarly disfigured with black teeth, though not yet to the hideous extent common among their more civilised, or, rather, less savage, neighbours. They likewise now imitate the latter in respect to clothing, the men adopting the narrow loin cloth and the women a small cloth skirt.

Their dwellings are small, and cannot compare with those of the coast people, and are indeed but little, if at all, superior to those of the Negritos in Little Andaman, but they more nearly assimilate the former in design as well as mode of construction, for they are erected on posts; the floors being raised six or seven feet above the ground necessitate the use of ladders.

It is impossible within the limits of this abstract to make further mention of the dwellings, or to describe the peculiar sack-like cooking vessels of this strange race.

It is, however, worthy of note that the Pen tribes—despite their low state of civilisation—are found capable of expressing high numerals; though the *terms* used are distinct, the *system* is apparently identical with that employed by the coast people.

Mr. Man hopes before long to be able to supplement in many particulars the rudimentary information which has hitherto been obtainable regarding the Peṅ, but the task is one of considerable difficulty, for, apart from the dread entertained by

this tribe towards aliens, their frequent feuds place from time to time a temporary barrier to all intercourse between them and our friends on the coast, through whom at present all our communications have to be conducted. The nearest portion of Great Nicobar island is, moreover, about 60 miles distant from the Government settlement at Nancowry.

---

11. *A proposed Society for Experimental Psychology.*[1] *By* JOSEPH JACOBS, *B.A.*

Though this is the age of societies, there is no organised association in England devoted to the interest of the science of mind. Yet there is plenty of scope for such a society. Psychology has itself reached what may be termed the monographic stage, and there are besides several sciences which are independently treating various branches of mental science, *e.g.* neuro-physiology, folklore and analogous branches of anthropology, social statistics and *Völkerpsychologie*, comparative syntax, and the doctrine of insanity. There is thus plenty of work to do, and London University has trained a number of workers. Psychologists had a separate journal (*Mind*); why should they not have a separate society? This would offer the usual advantages of a *local*, library, opportunities of meeting for fellow-students, publication of memoirs, *Jahresberichten*, bibliographies, &c. It would have important work to do in settling the scope, terminology, and divisions of the science. But, above all, there was one particular function which such a society could perform which made its existence more desirable than in any other subject. The members of the society would be made to form its own laboratory: their minds might be utilised as materials on which to work. Full membership might be held to imply readiness to aid in special investigation, by answering queries issued by properly constituted organs of the society. Thus, any member desiring to study comparatively any problem in which introspection was involved, would state his wants to the general committee. This body, if the subject were thought worthy of it, would appoint a sub-committee (to which the member in question would act as honorary secretary) to investigate the matter, and they would be empowered to address specific inquiries on the subject to the members of the society. By this means the chief hindrance to the progress of the science, the subjective and personal character of the results of individual inquiry, would be removed, if such a scheme could be got into working order.

Mr. Galton's experience in his investigations on imagination had shown the practicability of such a method of inquiry. And with regard to the question as to the subjects which lent themselves to such investigations, the difficulty would rather be to pick out the most important from the many which would suggest themselves to trained psychologists. Among many others might be numbered the whole field of psycho-physical research, now developed into a separate branch of psychology by Fechner, Wundt, and others, and the observation of children begun by Darwin and developed by Taine, Perez, Preyer, and others. The collection of actual trains of association, the extent of the field of attention, after-images, colour-blindness and note-deafness, will-practice, how family traits are set, and by whom—these and a hundred analogous topics would receive elucidation by the adoption of this plan. It might be hoped that we might soon be enabled to measure the mental qualities of individuals almost as accurately as we can now measure their physical ones.

As an instance of such an inquiry, which might even deserve the attention of a Psychometric Committee of the British Association, reference might be made to some recent investigations on verbal memory by a German author, Dr. Ebbinghaus. By careful examination of the conditions under which he could reproduce unmeaning words of various lengths, he had been able to deduce quantitative laws for memory. In addition to these, the author of the paper had deduced the following relations from Ebbinghaus' results. There is for everyone a limited number ot unmeaning syllables which he can repeat after one hearing; this number the author

[1] Published *in extenso, Mind.* Jan 1886.

proposed to call 'the threshold of memory.' He had deduced from Ebbinghaus' results that for every syllable over the threshold three repetitions of the word are required to ensure that it be accurately remembered. Thus, a person whose threshold is six syllables would know Shakespeare's longest word, *Honorificabilitudinitatibus,* after repeating it twenty-one times; one whose threshold value was eight could repeat it after fifteen repetitions; and so on. Just at present this curious result was based only on a single investigation. If a Psychological Society were in existence its validity would be at once tested.

The practical utility of such inquiries would be at once evident on reflecting on the gain which would accrue to education if some method could be obtained by which children's minds (*e.g.* their 'threshold of memory') could be measured on entry into school and at various intervals afterwards. And, looking wider, if the art of conduct is ever to be based on scientific grounds, it will be from psychology that it will seek its data. The final end of the British Association itself might be said to be the formation of good characters, and yet such is the chaotic state of psychological investigation that we cannot give even a provisional account of what constitutes a good character, or even define accurately what are the ingredients of character generally. The formation of a Psychological Society on the lines suggested in this paper would certainly do something in advancing these ends and removing these obscurities.

---

12. *A Comparative Estimate of Jewish Ability.*[1] *By* JOSEPH JACOBS, *B.A.*

This is a parallel investigation to that of Mr. Galton in his 'Hereditary Genius,' based, as is well known, on an application of the law of error to the data given in dictionaries of contemporary biography. From these Mr. Galton had calculated that in every million of Englishmen over fifty there would be one man of preeminent excellence (class X), 14 of eminent ability (class G), and 233 of ability equal to that of an English judge (class F). By two independent methods the author had ascertained that almost exactly one million Jews had reached the age of fifty in the century 1785–1885. The problem is to find how many of these would be included in the above classes of ability. In all, 335 names of Jewish celebrities had been collected from the various dictionaries of contemporary biography (Cooper, Vapereau, Gubernatis). Of these, 166 were rejected as of fourth-class ability (E), being 10 per cent. more than were rejected in Mr. Galton's investigations. Of the remaining 169, four were classed as X (B. Disraeli, H. Heine, F. Lassalle, F. B. Mendelssohn), 20 as G (Auerbach, Benfey, Börne, Cremieux, E. Gans, A. Geiger, H. Gratz, Halevy, Sir W. Herschel, Jacobi, Sir G. Jessel, Lasker, Lazarus, S. Maimon, K. Marx, Meyerbeer, Neander, J. Oppert, Sir F. C. Palgrave, Rachel, Ricardo, Jules Simon, Steinschneider, Steinthal, Sylvester, Zunc), and 142 as F. The numbers in the first two classes were superior to the results for Englishmen, and would seem to imply superior ability in Jews. The third, however, was far below the normal value, which may be attributed to the restrictions under which Jews have laboured: these would tend to keep down third-class powers more than those of the other two classes. This explanation is confirmed by the numbers of celebrities before and after emancipation in various countries, and especially by the case of Russia, where two-thirds of European Jews live, and which yet contributes only nine names to the list, of whom five were rejected, and the remaining four only reached class F. The general result seemed to be that there was a considerably greater chance of finding distinguished men among a million Jews than among a million Englishmen. But this result has to be modified by the consideration that nearly all Jews live in towns, and the comparison therefore ought to be with the Englishmen of cities.

Turning from the numbers who reach eminence to the subjects in which eminence is reached, the following results were obtained. No Jews were distinguished as agriculturists, engravers, or sailors; fewer Jews, as compared with

[1] Published *in extenso, Journ. Anthrop. Inst.* Feb. 1886.

Englishmen, reached eminence in authorship, divinity, engineering, the army, as statesmen, or as travellers; while more Jews than Englishmen obtained fame as actors, chessplayers, doctors, merchants, metaphysicians, musicians, poets, and philologists. The percentages were about equal for antiquaries, architects, artists, lawyers, scientists, political economists, and sculptors. These results seem to confirm popular impressions, except as regards the equal capacity of Jews for art and science, in which they are generally thought inferior. Among other results deduced from the list, were that Jews of Spanish descent showed greater ability than their German brethren, and that the offspring of mixed marriages showed greater ability than either; the most marked superiority of Jews over Englishmen was in philology, where they numbered ten times as many, and in music, where they showed sevenfold proficiency.

What are the causes which render Jews, though hitherto so hampered in the struggle for fame, capable, to say the least, of holding their own when compared with Englishmen? The following may be mentioned: the intelligence of dissenters generally, their life in cities, their care for education in the past and present, the study of Hebrew as training in linguistics, the undogmatic nature of Judaism, the encouragement given to young men of talent. And it must be remembered that, in the past, every generation has been weeded of its weak-kneed members, who have been tempted or forced to become Christians, so that contemporary Jews are the outcome of a long process of unnatural selection.

It is perhaps unnecessary to add that the present estimate is necessarily one-sided, though every precaution has been taken by the author to remove subjective bias in dealing with this question. At any rate, the results obtained, though favourable to Jews, cannot be regarded as opposed to general impressions.

---

13. *Traces of Early Human Habitations on Deeside and Vicinity. By the* Rev. J. G. Michie, *A.M.*

Circular Cairns:—Their structure. Their probable uses—human dwellings; sepulchral purposes. Urns, chests (cists) found in connection (Migvie).

Yerd Houses:—General structure—examples in Cromar, Glenkindy, and Kildrummy. Probable uses. Generally found in the vicinity of round cairns and circular foundations.

Lake Dwellings (Crannogs):—Island in Loch Kinnord, Loch of Leys. Similar to those found in Wigtonshire and Ayrshire. Dr. Stuart's 'Scottish Crannogs,' and Dr. Munroe's 'Ancient Scottish Lake Dwellings.' Relics found in connection—canoes, arrow-heads, celts, stone knives, and stone cups.

Moated Forts:—Lumphanan, Invernochty, Rothiemurchus, and ruder form at Loch Davan.

Ancient Pictish Towns:—Character, and situation. Davan—Short description of; probably the *Devana* of the Romans.

'The information conveyed under the two first headings is, in great part, new; but the general conclusion is not much different from that of previous writers on these subjects.

'The authorities adduced for the observations under the third heading are given in the Abstract. The author's own explorations point very much in the direction of those of previous investigators.

'Under the heading Moated Forts, the writer advocates the more extensive and careful exploration of these remains; and from such he anticipates important elucidation of our early historic period.

'The last heading is an abridged excerpt from the author's work: "History of Loch Kinnord, *D. Douglas*, 1877, pp. 23, 45."'

INDEX.

[*An asterisk* (*) *signifies that no abstract of the communication is given.*]

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Life Members (since 1845), and all Annual Members who have not intermitted their Subscription, receive gratis all Reports published after the date of their Membership. Any other volume they require may be obtained on application at the Office of the Association, 22 Albemarle Street, Piccadilly, London, W., at the following prices, viz.—Reports for 1831 to 1874 (*of which more than* 15 *copies remain*), at 2*s.* 6*d.* per volume; after that date, at two-thirds of the Publication Price. A few sets, from 1831 to 1874 inclusive, may also be obtained at £10 per set.

Associates for the Meeting in 1885 may obtain the Volume for the Year at two-thirds of the Publication Price.

PROCEEDINGS OF THE FIRST AND SECOND MEETINGS, at York and Oxford, 1831 and 1832, *Published at* 13*s.* 6*d.*

CONTENTS:—Prof. Airy, on the Progress of Astronomy;—J. W. Lubbock, on the Tides;—Prof. Forbes, on the Present State of Meteorology;—Prof. Powell, on the Present State of the Science of Radiant Heat;—Prof. Cumming, on Thermo-Electricity;—Sir D. Brewster, on the Progress of Optics;—Rev. W. Whewell, on the Present State of Mineralogy;—Rev. W. D. Conybeare, on the Recent Progress and Present State of Geology;—Dr. Pritchard's Review of Philological and Physical Researches.

Together with Papers on Mathematics, Optics, Acoustics, Magnetism, Electricity, Chemistry, Meteorology, Geography, Geology, Zoology, Anatomy, Physiology, Botany, and the Arts; and an Exposition of the Objects and Plan of the Association, &c.

PROCEEDINGS OF THE THIRD MEETING, at Cambridge, 1833, *Published at* 12*s.* (Out of Print.)

CONTENTS:—Proceedings of the Meeting;—John Taylor, on Mineral Veins;—Dr. Lindley, on the Philosophy of Botany;—Dr. Henry, on the Physiology of the Nervous System;—P. Barlow, on the Strength of Materials;—S. H. Christie, on the Magnetism of the Earth;—Rev. J. Challis, on the Analytical Theory of Hydrostatics and Hydrodynamics;—G. Rennie, on Hydraulics as a Branch of Engineering, Part I.;—Rev. G. Peacock, on certain Branches of Analysis.

Together with Papers on Mathematics and Physics, Philosophical Instruments and Mechanical Arts, Natural History, Anatomy, Physiology, and History of Science.

PROCEEDINGS OF THE FOURTH MEETING, at Edinburgh, 1834, *Published at* 15*s*.

CONTENTS:—H. G. Rogers, on the Geology of North America;—Dr. C. Henry, on the Laws of Contagion;—Prof. Clark, on Animal Physiology;—Rev. L. Jenyns, on Zoology;—Rev. J. Challis, on Capillary Attraction;—Prof. Lloyd, on Physical Optics;—G. Rennie, on Hydraulics, Part II.

Together with the Transactions of the Sections, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FIFTH MEETING, at Dublin, 1835, *Published at* 13*s*. 6*d*. (Out of Print.)

CONTENTS:—Rev. W. Whewell, on the Recent Progress and Present Condition of the Mathematical Theories of Electricity, Magnetism, and Heat;—A. Quetelet, Aperçu de l'Etat actuel des Sciences Mathématiques chez les Belges;—Capt. E. Sabine, on the Phenomena of Terrestrial Magnetism.

Together with the Transactions of the Sections, Prof. Sir W. Hamilton's Address and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE SIXTH MEETING, at Bristol, 1836, *Published at* 12*s*. (Out of Print.)

CONTENTS:—Prof. Daubeny, on the Present State of our Knowledge with respect to Mineral and Thermal Waters;—Major E. Sabine, on the Direction and Intensity of the Terrestrial Magnetic Force in Scotland;—J. Richardson, on North American Zoology;—Rev. J. Challis, on the Mathematical Theory of Fluids;—J. T. Mackay, a Comparative View of the more remarkable Plants which characterize the neighbourhood of Dublin and Edinburgh, and the South-west of Scotland, &c.;—J. T. Mackay, Comparative Geographical Notices of the more remarkable Plants which characterize Scotland and Ireland;—Report of the London Sub-Committee of the Medical Section on the Motions and Sounds of the Heart;—Second Report of the Dublin Sub-Committee on the Motions and Sounds of the Heart;—Report of the Dublin Committee on the Pathology of the Brain and Nervous System;—J. W. Lubbock, Account of the Recent Discussions of Observations of the Tides;—Rev. B. Powell, on determining the Refractive Indices for the Standard Rays of the Solar Spectrum in various media;—Dr. Hodgkin, on the Communication between the Arteries and Absorbents;—Prof. Phillips, Report of Experiments on Subterranean Temperature;—Prof. Hamilton, on the Validity of a Method recently proposed by G. B. Jerrard, for Transforming and Resolving Equations of Elevated Degrees.

Together with the Transactions of the Sections, Prof. Daubeny's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE SEVENTH MEETING, at Liverpool, 1837, *Published at* 16*s*. 6*d*. (Out of Print.)

CONTENTS:—Major E. Sabine, on the Variations of the Magnetic Intensity observed at different points of the Earth's Surface;—Rev. W. Taylor, on the various modes of Printing for the Use of the Blind;—J. W. Lubbock, on the Discussions of Observations of the Tides;—Prof. T. Thompson, on the Difference between the Composition of Cast Iron produced by the Cold and Hot Blast;—Rev. T. R. Robinson, on the Determination of the Constant of Nutation by the Greenwich Observations;—R. W. Fox, Experiments on the Electricity of Metallic Veins, and the Temperature of Mines;—Provisional Report of the Committee of the Medical Section of the British Association, appointed to investigate the Composition of Secretions, and the Organs producing them;—Dr. G. O. Rees, Report from the Committee for inquiring into the Analysis of the Glands, &c., of the Human Body;—Second Report of the London Sub-Committee of the British Association Medical Section, on the Motions and Sounds of the Heart;—Prof. Johnston, on the Present State of our Knowledge in regard to Dimorphous Bodies;—Lieut.-Col. Sykes, on the Statistics of the four Collectorates of Dukhun, under the British Government;—E. Hodgkinson, on the relative

Strength and other Mechanical Properties of Iron obtained from the Hot and Cold Blast;—W. Fairbairn, on the Strength and other Properties of Iron obtained from the Hot and Cold Blast;—Sir J. Robinson and J. S. Russell, Report of the Committee on Waves;—Note by Major Sabine, being an Appendix to his Report on the Variations of the Magnetic Intensity observed at different Points of the Earth's Surface —J. Yates, on the Growth of Plants under Glass, and without any free communication with the outward Air, on the Plan of Mr. N. J. Ward, of London.

Together with the Transactions of the Sections, Prof. Traill's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE EIGHTH MEETING, at Newcastle, 1838, *Published at* 15*s*. (Out of Print.)

CONTENTS:—Rev. W. Whewell, Account of a Level Line, measured from the Bristol Channel to the English Channel, by Mr. Bunt;—Report on the Discussions of Tides, prepared under the direction of the Rev. W. Whewell;—W. S. Harris, Account of the Progress and State of the Meteorological Observations at Plymouth;—Major E. Sabine, on the Magnetic Isoclinal and Isodynamic Lines in the British Islands; —Dr. Lardner, on the Determination of the Mean Numerical Values of Railway Constants;—R. Mallet, First Report upon Experiments upon the Action of Sea and River Water upon Cast and Wrought Iron;—R. Mallet, on the Action of a Heat of 212° Fahr., when long continued, on Inorganic and Organic Substances.

Together with the Transactions of the Sections, Mr. Murchison's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE NINTH MEETING, at Birmingham, 1839, *Published at* 13*s*. 6*d*. (Out of Print.)

CONTENTS:—Rev. B. Powell, Report on the Present State of our Knowledge of Refractive Indices, for the Standard Rays of the Solar Spectrum in different media; Report on the Application of the Sum assigned for Tide Calculations to Rev. W. Whewell, in a letter from T. G. Bunt, Esq.;—H. L. Pattinson, on some Galvanic Experiments to determine the Existence or Non-Existence of Electrical Currents among Stratified Rocks, particularly those of the Mountain Limestone formation, constituting the Lead Measures of Alton Moor;—Sir D. Brewster, Reports respecting the Two Series of Hourly Meteorological Observations kept in Scotland;—Report on the subject of a series of Resolutions adopted by the British Association at their Meeting in August 1838, at Newcastle;—R. Owen, Report on British Fossil Reptiles; —E. Forbes, Report on the Distribution of the Pulmoniferous Mollusca in the British Isles;—W. S. Harris, Third Report on the Progress of the Hourly Meteorological Register at Plymouth Dockyard.

Together with the Transactions of the Sections, Rev. W. Vernon Harcourt's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TENTH MEETING, at Glasgow, 1840, *Published at* 15*s*. (Out of Print.)

CONTENTS:—Rev. B. Powell, Report on the Recent Progress of discovery relative to Radiant Heat, supplementary to a former Report on the same subject inserted in the first volume of the Reports of the British Association for the Advancement of Science;—J. D. Forbes, Supplementary Report on Meteorology;—W. S. Harris, Report on Prof. Whewell's Anemometer, now in operation at Plymouth;—Report on 'The Motion and Sounds of the Heart,' by the London Committee of the British Association, for 1839-40;—Prof. Schönbein, an Account of Researches in Electro-Chemistry;—R. Mallet, Second Report upon the Action of Air and Water, whether fresh or salt, clear or foul, and at various temperatures, upon Cast Iron, Wrought Iron, and Steel;—R. W. Fox, Report on some Observations on Subterranean Temperature;—A. F. Osler, Report on the Observations recorded during the years 1837, 1838, 1839, and 1840, by the Self-registering Anemometer erected at the Philosophical Institution, Birmingham;—Sir D. Brewster, Report respecting the Two Series of Hourly Meteorological Observations kept at Inverness and Kingussie, from Nov. 1st, 1838, to Nov. 1st, 1839;—W. Thompson, Report on the Fauna of Ireland: Div. *Verte-*

brata;—C. J. B. Williams, M.D., Report of Experiments on the Physiology of the Lungs and Air-Tubes;—Rev. J. S. Henslow, Report of the Committee on the Preservation of Animal and Vegetable Substances.

Together with the Transactions of the Sections, Mr. Murchison and Major E. Sabine's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE ELEVENTH MEETING, at Plymouth, 1841, *Published at* 13*s.* 6*d.*

CONTENTS:—Rev. P. Kelland, on the Present State of our Theoretical and Experimental Knowledge of the Laws of Conduction of Heat;—G. L. Roupell, M.D., Report on Poisons;—T. G. Bunt, Report on Discussions of Bristol Tides, under the direction of the Rev. W. Whewell;—D. Ross, Report on the Discussions of Leith Tide Observations, under the direction of the Rev. W. Whewell;—W. S. Harris, upon the working of Whewell's Anemometer at Plymouth during the past year;—Report of a Committee appointed for the purpose of superintending the scientific co-operation of the British Association in the System of Simultaneous Observations in Terrestrial Magnetism and Meteorology;—Reports of Committees appointed to provide Meteorological Instruments for the use of M. Agassiz and Mr. M'Cord;—Report of a Committee appointed to superintend the Reduction of Meteorological Observations;—Report of a Committee for revising the Nomenclature of the Stars;—Report of a Committee for obtaining Instruments and Registers to record Shocks and Earthquakes in Scotland and Ireland;—Report of a Committee on the Preservation of Vegetative Powers in Seeds;—Dr. Hodgkin, on Inquiries into the Races of Man;—Report of the Committee appointed to report how far the Desiderata in our knowledge of the Condition of the Upper Strata of the Atmosphere may be supplied by means of Ascents in Balloons or otherwise, to ascertain the probable expense of such Experiments, and to draw up Directions for Observers in such circumstances;—R. Owen, Report on British Fossil Reptiles;—Reports on the Determination of the Mean Value of Railway Constants;—Dr. D. Lardner, Second and concluding Report on the Determination of the Mean Value of Railway Constants;—E. Woods, Report on Railway Constants;—Report of a Committee on the Construction of a Constant Indicator for Steam Engines.

Together with the Transactions of the Sections, Prof. Whewell's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWELFTH MEETING, at Manchester, 1842, *Published at* 10*s.* 6*d.*

CONTENTS:—Report of the Committee appointed to conduct the co-operation of the British Association in the System of Simultaneous Magnetical and Meteorological Observations;—Dr. J. Richardson, Report on the present State of the Ichthyology of New Zealand;—W. S. Harris, Report on the Progress of Meteorological Observations at Plymouth;—Second Report of a Committee appointed to make Experiments on the Growth and Vitality of Seeds;—C. Vignoles, Report of the Committee on Railway Sections;—Report of the Committee for the Preservation of Animal and Vegetable Substances;—Dr. Lyon Playfair, Abstract of Prof. Liebig's Report on Organic Chemistry applied to Physiology and Pathology;—R. Owen, Report on the British Fossil Mammalia, Part I.;—R. Hunt, Researches on the Influence of Light on the Germination of Seeds and the Growth of Plants;—L. Agassiz, Report on the Fossil Fishes of the Devonian System or Old Red Sandstone;—W. Fairbairn, Appendix to a Report on the Strength and other Properties of Cast Iron obtained from the Hot and Cold Blast;—D. Milne, Report of the Committee for Registering Shocks of Earthquakes in Great Britain;—Report of a Committee on the construction of a Constant Indicator for Steam-Engines, and for the determination of the Velocity of the Piston of the Self-acting Engine at different periods of the Stroke;—J. S. Russell, Report of a Committee on the Form of Ships;—Report of a Committee appointed 'to consider of the Rules by which the Nomenclature of Zoology may be established on a uniform and permanent basis;'—Report of a Committee on the Vital Statistics of Large Towns in Scotland;—Provisional Reports, and Notices of Progress in Special Researches entrusted to Committees and Individuals.

Together with the Transactions of the Sections, Lord Francis Egerton's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTEENTH MEETING, at Cork, 1843, *Published at* 12*s.*

CONTENTS:—Robert Mallet, Third Report upon the Action of Air and Water, whether fresh or salt, clear or foul, and at Various Temperatures, upon Cast Iron, Wrought Iron, and Steel;—Report of the Committee appointed to conduct the Co-operation of the British Association in the System of Simultaneous Magnetical and Meteorological Observations;—Sir J. F. W. Herschel, Bart., Report of the Committee appointed for the Reduction of Meteorological Observations;—Report of the Committee appointed for Experiments on Steam-Engines;—Report of the Committee appointed to continue their Experiments on the Vitality of Seeds;—J. S. Russell, Report of a Series of Observations on the Tides of the Frith of Forth and the East Coast of Scotland;—J. S. Russell, Notice of a Report of the Committee on the Form of Ships;—J. Blake, Report on the Physiological Action of Medicines;—Report of the Committee on Zoological Nomenclature;—Report of the Committee for Registering the Shocks of Earthquakes, and making such Meteorological Observations as may appear to them desirable;—Report of the Committee for conducting Experiments with Captive Balloons;—Prof. Wheatstone, Appendix to the Report;—Report of the Committee for the Translation and Publication of Foreign Scientific Memoirs;—C. W. Peach, on the Habits of the Marine Testacea;—E. Forbes, Report on the Mollusca and Radiata of the Ægean Sea, and on their distribution, considered as bearing on Geology;—L. Agassiz, Synoptical Table of British Fossil Fishes, arranged in the order of the Geological Formations;—R. Owen, Report on the British Fossil Mammalia, Part II.;—E. W. Binney, Report on the excavation made at the junction of the Lower New Red Sandstone with the Coal Measures at Collyhurst;—W. Thompson, Report on the Fauna of Ireland: Div. *Invertebrata;*—Provisional Reports, and Notices of Progress in Special Researches entrusted to Committees and Individuals.

Together with the Transactions of the Sections, the Earl of Rosse's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FOURTEENTH MEETING, at York, 1844, *Published at* £1.

CONTENTS:—W. B. Carpenter, on the Microscopic Structure of Shells;—J. Alder and A. Hancock, Report on the British Nudibranchiate Mollusca;—R. Hunt, Researches on the Influence of Light on the Germination of Seeds and the Growth of Plants;—Report of a Committee appointed by the British Association in 1840, for revising the Nomenclature of the Stars;—Lt.-Col. Sabine, on the Meteorology of Toronto in Canada;—J. Blackwall, Report on some recent researches into the Structure, Functions, and Economy of the *Araneidea* made in Great Britain;—Earl of Rosse, on the Construction of large Reflecting Telescopes;—Rev. W. V. Harcourt, Report on a Gas-furnace for Experiments on Vitrifaction and other Applications of High Heat in the Laboratory;—Report of the Committee for Registering Earthquake Shocks in Scotland;—Report of a Committee for Experiments on Steam-Engines;—Report of the Committee to investigate the Varieties of the Human Race;—Fourth Report of a Committee appointed to continue their Experiments on the Vitality of Seeds;—W. Fairbairn, on the Consumption of Fuel and the Prevention of Smoke;—F. Ronalds, Report concerning the Observatory of the British Association at Kew;—Sixth Report of the Committee appointed to conduct the Co-operation of the British Association in the System of Simultaneous Magnetical and Meteorological Observations;—Prof. Forchhammer on the influence of Fucoidal Plants upon the Formations of the Earth, on Metamorphism in general, and particularly the Metamorphosis of the Scandinavian Alum Slate;—H. E. Strickland, Report on the Recent Progress and Present State of Ornithology;—T. Oldham, Report of Committee appointed to conduct Observations on Subterranean Temperature in Ireland;—Prof. Owen, Report on the Extinct Mammals of Australia, and descriptions of certain Fossils indicative of the former existence in that continent of large Marsupial Representatives of the Order Pachydermata;—W. S. Harris, Report on the working of Whewell and Osler's Anemometers at Plymouth, for the years 1841, 1842, 1843;—W. R. Birt, Report on Atmospheric Waves;—L. Agassiz, Rapport sur les Poissons Fossiles de l'Argile de Londres, with translation;—J. S.

Russell, Report on Waves;—Provisional Reports, and Notices of Progress in Special Researches entrusted to Committees and Individuals.

Together with the Transactions of the Sections, the Dean of Ely's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FIFTEENTH MEETING, at Cambridge, 1845, *Published at* 12*s.*

CONTENTS:—Seventh Report of a Committee appointed to conduct the Co-operation of the British Association in the System of Simultaneous Magnetical and Meteorological Observations;—Lieut.-Col. Sabine, on some Points in the Meteorology of Bombay;—J. Blake, Report on the Physiological Actions of Medicines;—Dr. Von Boguslawski, on the Comet of 1843;—R. Hunt, Report on the Actinograph;—Prof. Schönbein, on Ozone;—Prof. Erman, on the Influence of Friction upon Thermo-Electricity;—Baron Senftenberg, on the Self-registering Meteorological Instruments employed in the Observatory at Senftenberg;—W. R. Birt, Second Report on Atmospheric Waves;—G. R. Porter, on the Progress and Present Extent of Savings' Banks in the United Kingdom;—Prof. Bunsen and Dr. Playfair, Report on the Gases evolved from Iron Furnaces, with reference to the Theory of Smelting of Iron;—Dr. Richardson, Report on the Ichthyology of the Seas of China and Japan;—Report of the Committee on the Registration of Periodical Phenomena of Animals and Vegetables;—Fifth Report of the Committee on the Vitality of Seeds;—Appendix, &c.

Together with the Transactions of the Sections, Sir J. F. W. Herschel's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE SIXTEENTH MEETING, at Southampton, 1846, *Published at* 15*s.*

CONTENTS:—G. G. Stokes, Report on Recent Researches in Hydrodynamics;—Sixth Report of the Committee on the Vitality of Seeds;—Dr. Schunck, on the Colouring Matters of Madder;—J. Blake, on the Physiological Action of Medicines;—R. Hunt, Report on the Actinograph;—R. Hunt, Notices on the Influence of Light on the Growth of Plants;—R. L. Ellis, on the Recent Progress of Analysis;—Prof. Forchhammer, on Comparative Analytical Researches on Sea Water;—A. Erman, on the Calculation of the Gaussian Constants for 1829;—G. R. Porter, on the Progress, present Amount, and probable future Condition of the Iron Manufacture in Great Britain;—W. R. Birt, Third Report on Atmospheric Waves;—Prof. Owen, Report on the Archetype and Homologies of the Vertebrate Skeleton;—J. Phillips, on Anemometry;—Dr. J. Percy, Report on the Crystalline Flags;—Addenda to Mr. Birt's Report on Atmospheric Waves.

Together with the Transactions of the Sections, Sir R. I. Murchison's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE SEVENTEENTH MEETING, at Oxford, 1847, *Published at* 18*s.*

CONTENTS:—Prof. Langberg, on the Specific Gravity of Sulphuric Acid at different degrees of dilution, and on the relation which exists between the Development of Heat and the coincident contraction of Volume in Sulphuric Acid when mixed with Water;—R. Hunt, Researches on the Influence of the Solar Rays on the Growth of Plants;—R. Mallet, on the Facts of Earthquake Phenomena;—Prof. Nilsson, on the Primitive Inhabitants of Scandinavia;—W. Hopkins, Report on the Geological Theories of Elevation and Earthquakes;—Dr. W. B. Carpenter, Report on the Microscopic Structure of Shells;—Rev. W. Whewell and Sir James C. Ross, Report upon the Recommendation of an Expedition for the purpose of completing our Knowledge of the Tides;—Dr. Schunck, on Colouring Matters;—Seventh Report of the Committee on the Vitality of Seeds;—J. Glynn, on the Turbine or Horizontal Water-Wheel of France and Germany;—Dr. R. G. Latham, on the present state and

recent progress of Ethnographical Philology;—Dr. J. C. Prichard, on the various methods of Research which contribute to the Advancement of Ethnology, and of the relations of that Science to other branches of Knowledge;—Dr. C. C. J. Bunsen, on the results of the recent Egyptian researches in reference to Asiatic and African Ethnology, and the Classification of Languages;—Dr. C. Meyer, on the Importance of the Study of the Celtic Language as exhibited by the Modern Celtic Dialects still extant;—Dr. Max Müller, on the Relation of the Bengali to the Aryan and Aboriginal Languages of India;—W. R. Birt, Fourth Report on Atmospheric Waves;—Prof. W. H. Dove, Temperature Tables, with Introductory Remarks by Lieut.-Col. E. Sabine;—A. Erman and H. Petersen, Third Report on the Calculation of the Gaussian Constants for 1829.

Together with the Transactions of the Sections, Sir Robert Harry Inglis's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE EIGHTEENTH MEETING, at Swansea, 1848, *Published at* 9*s*.

CONTENTS:—Rev. Prof. Powell, A Catalogue of Observations of Luminous Meteors;—J. Glynn, on Water-pressure Engines;—R. A. Smith, on the Air and Water of Towns;—Eighth Report of Committee on the Growth and Vitality of Seeds;—W. R. Birt, Fifth Report on Atmospheric Waves;—E. Schunck, on Colouring Matters;—J. P. Budd, on the advantageous use made of the gaseous escape from the Blast Furnaces at the Ystalyfera Iron Works;—R. Hunt, Report of progress in the investigation of the Action of Carbonic Acid on the Growth of Plants allied to those of the Coal Formations;—Prof. H. W. Dove, Supplement to the Temperature Tables printed in the Report of the British Association for 1847;—Remarks by Prof. Dove on his recently constructed Maps of the Monthly Isothermal Lines of the Globe, and on some of the principal Conclusions in regard to Climatology deducible from them; with an introductory Notice by Lieut.-Col. E. Sabine;—Dr. Daubeny, on the progress of the investigation on the Influence of Carbonic Acid on the Growth of Ferns;—J. Phillips, Notice of further progress in Anemometrical Researches;—Mr. Mallet's Letter to the Assistant-General Secretary;—A. Erman, Second Report on the Gaussian Constants;—Report of a Committee relative to the expediency of recommending the continuance of the Toronto Magnetical and Meteorological Observatory until December 1850.

Together with the Transactions of the Sections, the Marquis of Northampton's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE NINETEENTH MEETING, at Birmingham, 1849, *Published at* 10*s*.

CONTENTS:—Rev. Prof. Powell, A Catalogue of Observations of Luminous Meteors;—Earl of Rosse, Notice of Nebulæ lately observed in the Six-feet Reflector;—Prof. Daubeny, on the Influence of Carbonic Acid Gas on the health of Plants, especially of those allied to the Fossil Remains found in the Coal Formation;—Dr. Andrews, Report on the Heat of Combination;—Report of the Committee on the Registration of the Periodic Phenomena of Plants and Animals;—Ninth Report of Committee on Experiments on the Growth and Vitality of Seeds;—F. Ronalds, Report concerning the Observatory of the British Association at Kew, from Aug. 9, 1848 to Sept. 12, 1849;—R. Mallet, Report on the Experimental Inquiry on Railway Bar Corrosion;—W. R. Birt, Report on the Discussion of the Electrical Observations at Kew.

Together with the Transactions of the Sections, the Rev. T. R. Robinson's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTIETH MEETING, at Edinburgh, 1850, *Published at* 15*s*. (Out of Print.)

CONTENTS:—R. Mallet, First Report on the Facts of Earthquake Phenomena;—Rev. Prof. Powell, on Observations of Luminous Meteors;—Dr. T. Williams, on the Structure and History of the British Annelida;—T. C. Hunt, Results of Meteorological Observations taken at St. Michael's from the 1st of January, 1840, to the 31st

of December, 1849;—R. Hunt, on the present State of our Knowledge of the Chemical Action of the Solar Radiations;—Tenth Report of Committee on Experiments on the Growth and Vitality of Seeds;—Major-Gen. Briggs, Report on the Aboriginal Tribes of India;—F. Ronalds, Report concerning the Observatory of the British Association at Kew;—E. Forbes, Report on the Investigation of British Marine Zoology by means of the Dredge;—R. MacAndrew, Notes on the Distribution and Range in depth of Mollusca and other Marine Animals, observed on the coasts of Spain, Portugal, Barbary, Malta, and Southern Italy in 1849;—Prof. Allman, on the Present State of our Knowledge of the Freshwater Polyzoa;—Registration of the Periodical Phenomena of Plants and Animals;—Suggestions to Astronomers for the Observation of the Total Eclipse of the Sun on July 28, 1851.

Together with the Transactions of the Sections, Sir David Brewster's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-FIRST MEETING, at Ipswich, 1851, *Published at* 16*s.* 6*d.*

CONTENTS:—Rev. Prof. Powell, on Observations of Luminous Meteors;—Eleventh Report of Committee on Experiments on the Growth and Vitality of Seeds;—Dr. J. Drew, on the Climate of Southampton;—Dr. R. A. Smith, on the Air and Water of Towns: Action of Porous Strata, Water, and Organic Matter;—Report of the Committee appointed to consider the probable Effects in an Economical and Physical Point of View of the Destruction of Tropical Forests;—A. Henfrey, on the Reproduction and supposed Existence of Sexual Organs in the Higher Cryptogamous Plants;—Dr. Daubeny, on the Nomenclature of Organic Compounds;—Rev. Dr. Donaldson, on two unsolved Problems in Indo-German Philology;—Dr. T. Williams, Report on the British Annelida;—R. Mallet, Second Report on the Facts of Earthquake Phenomena;—Letter from Prof. Henry to Col. Sabine, on the System of Meteorological Observations proposed to be established in the United States;—Col. Sabine, Report on the Kew Magnetographs;—J. Welsh, Report on the Performance of his three Magnetographs during the Experimental Trial at the Kew Observatory;—F. Ronalds, Report concerning the Observatory of the British Association at Kew, from September 12, 1850, to July 31, 1851;—Ordnance Survey of Scotland.

Together with the Transactions of the Sections, Prof. Airy's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-SECOND MEETING, at Belfast, 1852, *Published at* 15*s.*

CONTENTS:—R. Mallet, Third Report on the Facts of Earthquake Phenomena;—Twelfth Report of Committee on Experiments on the Growth and Vitality of Seeds;—Rev. Prof. Powell, Report on Observations of Luminous Meteors, 1851–52;—Dr. Gladstone, on the Influence of the Solar Radiations on the Vital Powers of Plants;—A Manual of Ethnological Inquiry;—Col. Sykes, Mean Temperature of the Day, and Monthly Fall of Rain at 127 Stations under the Bengal Presidency;—Prof. J. D. Forbes, on Experiments on the Laws of the Conduction of Heat;—R. Hunt, on the Chemical Action of the Solar Radiations;—Dr. Hodges, on the Composition and Economy of the Flax Plant;—W. Thompson, on the Freshwater Fishes of Ulster;—W. Thompson, Supplementary Report on the Fauna of Ireland;—W. Wills, on the Meteorology of Birmingham;—J. Thomson, on the Vortex-Water-Wheel;—J. B. Lawes and Dr. Gilbert, on the Composition of Foods in relation to Respiration and the Feeding of Animals.

Together with the Transactions of the Sections, Colonel Sabine's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-THIRD MEETING, at Hull, 1853, *Published at* 10*s.* 6*d.*

CONTENTS:—Rev. Prof. Powell, Report on Observations of Luminous Meteors, 1852–53;—James Oldham, on the Physical Features of the Humber;—James Oldham, on the Rise, Progress, and Present Position of Steam Navigation in Hull;—

William Fairbairn, Experimental Researches to determine the Strength of Locomotive Boilers, and the causes which lead to Explosion;—J. J. Sylvester, Provisional Report on the Theory of Determinants;—Professor Hodges, M.D., Report on the Gases evolved in Steeping Flax, and on the Composition and Economy of the Flax Plant;—Thirteenth Report of Committee on Experiments on the Growth and Vitality of Seeds;—Robert Hunt, on the Chemical Action of the Solar Radiations;—Dr. John P. Bell, Observations on the Character and Measurements of Degradation of the Yorkshire Coast;—First Report of Committee on the Physical Character of the Moon's Surface, as compared with that of the Earth;—R. Mallet, Provisional Report on Earthquake Wave-Transits; and on Seismometrical Instruments;—William Fairbairn, on the Mechanical Properties of Metals as derived from repeated Meltings, exhibiting the maximum point of strength and the causes of deterioration;—Robert Mallet, Third Report on the Facts of Earthquake Phenomena (continued).

Together with the Transactions of the Sections, Mr. Hopkins's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-FOURTH MEETING, at Liverpool, 1854, *Published at* 18*s*.

CONTENTS:—R. Mallet, Third Report on the Facts of Earthquake Phenomena (continued);—Major-General Chesney, on the Construction and General Use of Efficient Life-Boats;—Rev. Prof. Powell, Third Report on the present State of our Knowledge of Radiant Heat;—Colonel Sabine, on some of the results obtained at the British Colonial Magnetic Observatories;—Colonel Portlock, Report of the Committee on Earthquakes, with their proceedings respecting Seismometers;—Dr. Gladstone, on the Influence of the Solar Radiations on the Vital Powers of Plants, Part 2;—Rev. Prof. Powell, Report on Observations of Luminous Meteors, 1853–54;—Second Report of the Committee on the Physical Character of the Moon's Surface;—W. G. Armstrong, on the Application of Water-Pressure Machinery;—J. B. Lawes and Dr. Gilbert, on the Equivalency of Starch and Sugar in Food;—Archibald Smith, on the Deviations of the Compass in Wooden and Iron Ships;—Fourteenth Report of Committee on Experiments on the Growth and Vitality of Seeds.

Together with the Transactions of the Sections, the Earl of Harrowby's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-FIFTH MEETING, at Glasgow, 1855, *Published at* 15*s*.

CONTENTS:—T. Dobson, Report on the Relation between Explosions in Coal-Mines and Revolving Storms;—Dr. Gladstone, on the Influence of the Solar Radiations on the Vital Powers of Plants growing under different Atmospheric Conditions, Part 3;—C. Spence Bate, on the British Edriophthalma;—J. F. Bateman, on the present state of our knowledge on the Supply of Water to Towns;—Fifteenth Report of Committee on Experiments on the Growth and Vitality of Seeds;—Rev. Prof. Powell, Report on Observations of Luminous Meteors, 1854–55;—Report of Committee appointed to inquire into the best means of ascertaining those properties of Metals and effects of various modes of treating them which are of importance to the durability and efficiency of Artillery;—Rev. Prof. Henslow, Report on Typical Objects in Natural History;—A. Follett Osler, Account of the Self-registering Anemometer and Rain-Gauge at the Liverpool Observatory;—Provisional Reports.

Together with the Transactions of the Sections, the Duke of Argyll's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-SIXTH MEETING, at Cheltenham, 1856, *Published at* 18*s*.

CONTENTS:—Report from the Committee appointed to investigate and report upon the effects produced upon the Channels of the Mersey by the alterations which within the last fifty years have been made in its Banks;—J. Thomson, Interim Report on progress in Researches on the Measurement of Water by Weir Boards;—

Dredging Report, Frith of Clyde, 1856;—Rev. B. Powell, Report on Observations of Luminous Meteors, 1855–1856;—Prof. Bunsen and Dr. H. E. Roscoe, Photochemical Researches;—Rev. James Booth, on the Trigonometry of the Parabola, and the Geometrical Origin of Logarithms;—R. MacAndrew, Report on the Marine Testaceous Mollusca of the North-east Atlantic and neighbouring Seas, and the physical conditions affecting their development;—P. P. Carpenter, Report on the present state of our knowledge with regard to the Mollusca of the West Coast of North America;—T. C. Eyton, Abstract of First Report on the Oyster Beds and Oysters of the British Shores;—Prof. Phillips, Report on Cleavage, and Foliation in Rocks, and on the Theoretical Explanations of these Phenomena, Part 1;—Dr. T. Wright, on the Stratigraphical Distribution of the Oolitic Echinodermata;—W. Fairbairn, on the Tensile Strength of Wrought Iron at various Temperatures;—C. Atherton, on Mercantile Steam Transport Economy;—J. S. Bowerbank, on the Vital Powers of the Spongiadæ;—Report of a Committee upon the Experiments conducted at Stormontfield, near Perth, for the artificial propagation of Salmon;—Provisional Report on the Measurement of Ships for Tonnage;—On Typical Forms of Minerals, Plants and Animals for Museums;—J. Thomson, Interim Report on Progress in Researches on the Measurement of Water by Weir Boards;—R. Mallet, on Observations with the Seismometer;—A. Cayley, on the Progress of Theoretical Dynamics;—Report of a Committee appointed to consider the formation of a Catalogue of Philosophical Memoirs.

Together with the Transactions of the Sections, Dr. Daubeny's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-SEVENTH MEETING, at Dublin, 1857, *Published at* 15s.

CONTENTS:—A. Cayley, Report on the recent progress of Theoretical Dynamics;—Sixteenth and Final Report of Committee on Experiments on the Growth and Vitality of Seeds;—James Oldham, C.E., continuation of Report on Steam Navigation at Hull;—Report of a Committee on the Defects of the present methods of Measuring and Registering the Tonnage of Shipping, as also of Marine Engine-Power, and to frame more perfect rules, in order that a correct and uniform principle may be adopted to estimate the Actual Carrying Capabilities and Working-power of Steam Ships;—Robert Were Fox, Report on the Temperature of some Deep Mines in Cornwall;—Dr. G. Plarr, de quelques Transformations de la Somme $\Sigma_0^{-\alpha} \frac{\alpha^{t|+1}\beta^{t|+1}\delta^{t|+1}}{1^{t|+1}\gamma^{t|+1}\epsilon^{t|+1}}$ a étant entier négatif, et de quelques cas dans lesquels cette somme est exprimable par une combinaison de factorielles, la notation $\alpha^{t|+1}$ désignant le produit des facteurs $\alpha\ (\alpha+1)\ (\alpha+2)$ &c.... $(\alpha+t-1)$;—G. Dickie, M.D., Report on the Marine Zoology of Strangford Lough, County Down, and corresponding part of the Irish Channel;—Charles Atherton, Suggestions for Statistical Inquiry into the Extent to which Mercantile Steam Transport Economy is affected by the Constructive Type of Shipping, as respects the Proportions of Length, Breadth, and Depth;—J. S. Bowerbank, Further Report on the Vitality of the Spongiadæ;—Dr. John P. Hodges, on Flax;—Major-General Sabine, Report of the Committee on the Magnetic Survey of Great Britain;—Rev. Baden Powell, Report on Observations of Luminous Meteors, 1856–57;—C. Vignoles, on the Adaptation of Suspension Bridges to sustain the passage of Railway Trains;—Prof. W. A. Miller, on Electro-Chemistry;—John Simpson, Results of Thermometrical Observations made at the *Plover's* Wintering-place, Point Barrow, latitude 71° 21′ N., long. 156° 17′ W., in 1852–54;—Charles James Hargreave, on the Algebraic Couple; and on the Equivalents of Indeterminate Expressions;—Thomas Grubb, Report on the Improvement of Telescope and Equatorial Mountings;—Prof. James Buckman, Report on the Experimental Plots in the Botanical Garden of the Royal Agricultural College at Cirencester;—William Fairbairn, on the Resistance of Tubes to Collapse;—George C. Hyndman, Report of the Proceedings of the Belfast Dredging Committee;—Peter W. Barlow, on the Mechanical Effect of combining Girders and Suspension Chains, and a Comparison of the Weight of Metal in Ordinary and Suspension Girders, to produce equal deflections with a given load;—J. Park Harrison, Evidences of Lunar Influence on Temperature;—Report on the Animal and Vegetable Products imported into Liver-

pool from the year 1851 to 1855 (inclusive);—Andrew Henderson, Report on the Statistics of Life-boats and Fishing-boats on the Coasts of the United Kingdom.

Together with the Transactions of the Sections, the Rev. H. Lloyd's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-EIGHTH MEETING, at Leeds, September 1858, *Published at* 20s.

CONTENTS:—R. Mallet, Fourth Report upon the Facts and Theory of Earthquake Phenomena;—Rev. Prof. Powell, Report on Observations of Luminous Meteors, 1857–1858;—R. H. Meade, on some Points in the Anatomy of the Araneidea or true Spiders, especially on the internal structure of their Spinning Organs;—W. Fairbairn, Report of the Committee on the Patent Laws;—S. Eddy, on the Lead Mining Districts of Yorkshire;—W. Fairbairn, on the Collapse of Glass Globes and Cylinders;—Dr. E. Perceval Wright and Prof. J. Reay Greene, Report on the Marine Fauna of the South and West Coasts of Ireland;—Prof. J. Thomson, on Experiments on the Measurement of Water by Triangular Notches in Weir Boards;—Major-General Sabine, Report of the Committee on the Magnetic Survey of Great Britain;—Michael Connel and William Keddie, Report on Animal, Vegetable, and Mineral Substances imported from Foreign Countries into the Clyde (including the Ports of Glasgow, Greenock, and Port Glasgow) in the years 1853, 1854, 1855, 1856, and 1857;—Report of the Committee on Shipping Statistics;—Rev. H. Lloyd, D.D., Notice of the Instruments employed in the Magnetic Survey of Ireland, with some of the Results;—Prof. J. R. Kinahan, Report of Dublin Dredging Committee, appointed 1857–58;—Prof. J. R. Kinahan, Report on Crustacea of Dublin District;—Andrew Henderson, on River Steamers, their Form, Construction, and Fittings, with reference to the necessity for improving the present means of Shallow-Water Navigation on the Rivers of British India;—George C. Hyndman, Report of the Belfast Dredging Committee;—Appendix to Mr. Vignoles' Paper 'On the Adaptation of Suspension Bridges to sustain the passage of Railway Trains;'—Report of the Joint Committee of the Royal Society and the British Association, for procuring a continuance of the Magnetic and Meteorological Observatories;—R. Beckley, Description of a Self-recording Anemometer.

Together with the Transactions of the Sections, Prof. Owen's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE TWENTY-NINTH MEETING, at Aberdeen, September 1859, *Published at* 15s.

CONTENTS:—George C. Foster, Preliminary Report on the Recent Progress and Present State of Organic Chemistry;—Professor Buckman, Report on the Growth of Plants in the Garden of the Royal Agricultural College, Cirencester;—Dr. A. Voelcker, Report on Field Experiments and Laboratory Researches on the Constituents of Manures essential to Cultivated Crops;—A. Thomson, of Banchory, Report on the Aberdeen Industrial Feeding Schools;—On the Upper Silurians of Lesmahagow, Lanarkshire;—Alphonse Gages, Report on the Results obtained by the Mechanico-Chemical Examination of Rocks and Minerals;—William Fairbairn, Experiments to determine the Efficiency of Continuous and Self-acting Brakes for Railway Trains;—Professor J. R. Kinahan, Report of Dublin Bay Dredging Committee for 1858–59;—Rev. Baden Powell, Report on Observations of Luminous Meteors for 1858–59;—Professor Owen, Report on a Series of Skulls of various Tribes of Mankind inhabiting Nepal, collected, and presented to the British Museum, by Bryan H. Hodgson, Esq., late Resident in Nepal, &c. &c.;—Messrs. Maskelyne, Hadow, Hardwich, and Llewelyn, Report on the Present State of our Knowledge regarding the Photographic Image;—G. C. Hyndman, Report of the Belfast Dredging Committee for 1859;—James Oldham, Continuation of Report of the Progress of Steam Navigation at Hull;—Charles Atherton, Mercantile Steam Transport Economy as affected by the Consumption of Coals;—Warren De La Rue, Report on the present state of Celestial Photography in England;—Professor Owen, on the Orders of Fossil and Recent Reptilia, and their Distribution in Time;—Balfour Stewart, on some Results of the Magnetic Survey of Scotland in the years 1857 and 1858, undertaken, at the request of the British Association, by the late John Welsh, Esq., F.R.S.;—W. Fairbairn, The

Patent Laws: Report of Committee on the Patent Laws;—J. Park Harrison, Lunar Influence on the Temperature of the Air:—Balfour Stewart, an Account of the Construction of the Self-recording Magnetographs at present in operation at the Kew Observatory of the British Association;—Professor H. J. Stephen Smith, Report on the Theory of Numbers, Part I.;—Report of the Committee on Steamship Performance;—Report of the Proceedings of the Balloon Committee of the British Association appointed at the Meeting at Leeds;—Prof. William K. Sullivan, Preliminary Report on the Solubility of Salts at Temperatures above 100° Cent., and on the Mutual Action of Salts in Solution.

Together with the Transactions of the Sections, Prince Albert's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTIETH MEETING, at Oxford, June and July 1860, *Published at* 15*s*.

CONTENTS:—James Glaisher, Report on Observations of Luminous Meteors, 1859–60;—J. R. Kinahan, Report of Dublin Bay Dredging Committee;—Rev. J. Anderson, Report on the Excavations in Dura Den;—Prof. Buckman, Report on the Experimental Plots in the Botanical Garden of the Royal Agricultural College, Cirencester;—Rev. R. Walker, Report of the Committee on Balloon Ascents;—Prof. W. Thomson, Report of Committee appointed to prepare a Self-recording Atmospheric Electrometer for Kew, and Portable Apparatus for observing Atmospheric Electricity;—William Fairbairn, Experiments to determine the Effect of Vibratory Action and long-continued Changes of Load upon Wrought-iron Girders;—R. P. Greg, Catalogue of Meteorites and Fireballs, from A.D. 2 to A.D. 1860;—Prof. H. J. S. Smith, Report on the Theory of Numbers, Part II.;—Vice-Admiral Moorsom, on the Performance of Steam-vessels, the Functions of the Screw, and the Relations of its Diameter and Pitch to the Form of the Vessel;—Rev. W. V. Harcourt, Report on the Effects of long-continued Heat, illustrative of Geological Phenomena;—Second Report of the Committee on Steamship Performance;—Interim Report on the Gauging of Water by Triangular Notches;—List of the British Marine Invertebrate Fauna.

Together with the Transactions of the Sections, Lord Wrottesley's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-FIRST MEETING, at Manchester, September 1861, *Published at* £1.

CONTENTS:—James Glaisher, Report on Observations of Luminous Meteors;—Dr. E. Smith, Report on the Action of Prison Diet and Discipline on the Bodily Functions of Prisoners, Part I.;—Charles Atherton, on Freight as affected by Differences in the Dynamic Properties of Steamships;—Warren De La Rue, Report on the Progress of Celestial Photography since the Aberdeen Meeting;—B. Stewart, on the Theory of Exchanges, and its recent extension;—Drs. E. Schunck, R. Angus Smith, and H. E. Roscoe, on the Recent Progress and Present Condition of Manufacturing Chemistry in the South Lancashire District;—Dr. J. Hunt, on Ethno-Climatology; or, the Acclimatization of Man;—Prof. J. Thomson, on Experiments on the Gauging of Water by Triangular Notches;—Dr. A. Voelcker, Report on Field Experiments and Laboratory Researches on the Constituents of Manures essential to cultivated Crops;—Prof. H. Hennessy, Provisional Report on the Present State of our Knowledge respecting the Transmission of Sound-signals during Fogs at Sea;—Dr. P. L. Sclater and F. von Hochstetter, Report on the Present State of our Knowledge of the Birds of the Genus *Apteryx* living in New Zealand;—J. G. Jeffreys, Report of the Results of Deep-sea Dredging in Zetland, with a Notice of several Species of Mollusca new to Science or to the British Isles;—Prof. J. Phillips, Contributions to a Report on the Physical Aspect of the Moon;—W. R. Birt, Contribution to a Report on the Physical Aspect of the Moon;—Dr. Collingwood and Mr. Byerley, Preliminary Report of the Dredging Committee of the Mersey and Dee;—Third Report of the Committee on Steamship Performance;—J. G. Jeffreys, Preliminary Report on the Best Mode of preventing the Ravages of *Teredo* and other Animals in our Ships and Harbours;—R. Mallet, Report on the Experiments made at Holyhead to ascertain the Transit-Velocity of Waves, analogous to Earthquake Waves, through the local Rock Formations

—T. Dobson, on the Explosions in British Coal-Mines during the year 1859;—J. Oldham, Continuation of Report on Steam Navigation at Hull;—Prof. G. Dickie, Brief Summary of a Report on the Flora of the North of Ireland;—Prof. Owen, on the Psychical and Physical Characters of the Mincopies, or Natives of the Andaman Islands, and on the Relations thereby indicated to other Races of Mankind;—Colonel Sykes, Report of the Balloon Committee;—Major-General Sabine, Report on the Repetition of the Magnetic Survey of England;—Interim Report of the Committee for Dredging on the North and East Coasts of Scotland;—W. Fairbairn, on the Resistance of Iron Plates to Statical Pressure and the Force of Impact by Projectiles at High Velocities;—W. Fairbairn, Continuation of Report to determine the effect of Vibratory Action and long-continued Changes of Load upon Wrought-Iron Girders;—Report of the Committee on the Law of Patents;—Prof. H. J. S. Smith, Report on the Theory of Numbers, Part III.

Together with the Transactions of the Sections, Mr. Fairbairn's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-SECOND MEETING at Cambridge, October 1862, *Published at £1.*

CONTENTS:—James Glaisher, Report on Observations of Luminous Meteors, 1861–62;—G. B. Airy, on the Strains in the Interior of Beams;—Archibald Smith and F. J. Evans, Report on the three Reports of the Liverpool Compass Committee;—Report on Tidal Observations on the Humber;—T. Aston, on Rifled Guns and Projectiles adapted for Attacking Armour-plate Defences;—Extracts, relating to the Observatory at Kew, from a Report presented to the Portuguese Government, by Dr. J. A. de Souza;—H. T. Mennell, Report on the Dredging of the Northumberland Coast and Dogger Bank;—Dr. Cuthbert Collingwood, Report upon the best means of advancing Science through the agency of the Mercantile Marine;—Messrs. Williamson, Wheatstone, Thomson, Miller, Matthiessen, and Jenkin, Provisional Report on Standards of Electrical Resistance;—Preliminary Report of the Committee for investigating the Chemical and Mineralogical Composition of the Granites of Donegal;—Prof. H. Hennessy, on the Vertical Movements of the Atmosphere considered in connection with Storms and Changes of Weather;—Report of Committee on the application of Gauss's General Theory of Terrestrial Magnetism to the Magnetic Variations;—Fleeming Jenkin, on Thermo-electric Currents in Circuits of one Metal;—W. Fairbairn, on the Mechanical Properties of Iron Projectiles at High Velocities;—A. Cayley, Report on the Progress of the Solution of certain Special Problems of Dynamics;—Prof. G. G. Stokes, Report on Double Refraction;—Fourth Report of the Committee on Steamship Performance;—G. J. Symons, on the Fall of Rain in the British Isles in 1860 and 1861;—J. Ball, on Thermometric Observations in the Alps;—J. G. Jeffreys, Report of the Committee for Dredging on the North and East Coasts of Scotland;—Report of the Committee on Technical and Scientific Evidence in Courts of Law;—James Glaisher, Account of Eight Balloon Ascents in 1862;—Prof. H. J. S. Smith, Report on the Theory of Numbers, Part IV.

Together with the Transactions of the Sections, the Rev. Prof. R. Willis's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-THIRD MEETING, at Newcastle-upon-Tyne, August and September 1863, *Published at £1 5s.*

CONTENTS:—Report of the Committee on the Application of Gun-cotton to Warlike Purposes;—A. Matthiessen, Report on the Chemical Nature of Alloys;—Report of the Committee on the Chemical and Mineralogical Constitution of the Granites of Donegal, and on the Rocks associated with them;—J. G. Jeffreys, Report of the Committee appointed for exploring the Coasts of Shetland by means of the Dredge;—G. D. Gibb, Report on the Physiological Effects of the Bromide of Ammonium;—C. K. Aken, on the Transmutation of Spectral Rays, Part I.;—Dr. Robinson, Report of the Committee on Fog Signals;—Report of the Committee on Standards of Electrical Resistance;—E. Smith, Abstract of Report by the Indian Government on the Foods

used by the Free and Jail Populations in India ;—A. Gages, Synthetical Researches on the Formation of Minerals, &c. ;—R. Mallet, Preliminary Report on the Experimental Determination of the Temperatures of Volcanic Foci, and of the Temperature, State of Saturation, and Velocity of the issuing Gases and Vapours ;—Report of the Committee on Observations of Luminous Meteors ;—Fifth Report of the Committee on Steamship Performance ;—G. J. Allman, Report on the Present State of our Knowledge of the Reproductive System in the Hydroida ;—J. Glaisher, Account of Five Balloon Ascents made in 1863 ;—P. P. Carpenter, Supplementary Report on the Present State of our Knowledge with regard to the Mollusca of the West Coast of North America ;—Prof. Airy, Report on Steam Boiler Explosions ;—C. W. Siemens, Observations on the Electrical Resistance and Electrification of some Insulating Materials under Pressures up to 300 Atmospheres ;—C. M. Palmer, on the Construction of Iron Ships and the Progress of Iron Shipbuilding on the Tyne, Wear, and Tees ;—Messrs. Richardson, Stevenson, and Clapham, on the Chemical Manufactures of the Northern Districts ;—Messrs. Sopwith and Richardson, on the Local Manufacture of Lead, Copper, Zinc, Antimony, &c. ;—Messrs. Daglish and Forster, on the Magnesian Limestone of Durham ;—I. L. Bell, on the Manufacture of Iron in connexion with the Northumberland and Durham Coal-field ;—T. Spencer, on the Manufacture of Steel in the Northern District ;—Prof. H. J. S. Smith, Report on the Theory of Numbers, Part V.

Together with the Transactions of the Sections, Sir William Armstrong's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-FOURTH MEETING, at Bath, September 1864, *Published at* 18*s.*

CONTENTS :—Report of the Committee for Observations of Luminous Meteors ;—Report of the Committee on the best means of providing for a Uniformity of Weights and Measures ;—T. S. Cobbold, Report of Experiments respecting the Development and Migration of the Entozoa ;—B. W. Richardson, Report on the Physiological Action of Nitrite of Amyl ;—J. Oldham, Report of the Committee on Tidal Observations ;—G. S. Brady, Report on Deep-sea Dredging on the Coasts of Northumberland and Durham in 1864 ;—J. Glaisher, Account of Nine Balloon Ascents made in 1863 and 1864 ;—J. G. Jeffreys, Further Report on Shetland Dredgings ;—Report of the Committee on the Distribution of the Organic Remains of the North Staffordshire Coal-field ;—Report of the Committee on Standards of Electrical Resistance ;—G. J. Symons, on the Fall of Rain in the British Isles in 1862 and 1863 ;—W. Fairbairn, Preliminary Investigation of the Mechanical Properties of the proposed Atlantic Cable.

Together with the Transactions of the Sections, Sir Charles Lyell's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-FIFTH MEETING, at Birmingham, September 1865, *Published at* £1 5*s.*

CONTENTS :—J. G. Jeffreys, Report on Dredging among the Channel Isles ;—F. Buckland, Report on the Cultivation of Oysters by Natural and Artificial Methods ;—Report of the Committee for exploring Kent's Cavern ;—Report of the Committee on Zoological Nomenclature ;—Report on the Distribution of the Organic Remains of the North Staffordshire Coal-field ;—Report on the Marine Fauna and Flora of the South Coast of Devon and Cornwall ;—Interim Report on the Resistance of Water to Floating and Immersed Bodies ;—Report on Observations of Luminous Meteors ;—Report on Dredging on the Coast of Aberdeenshire ;—J. Glaisher, Account of Three Balloon Ascents ;—Interim Report on the Transmission of Sound under Water ;—G. J. Symons, on the Rainfall of the British Isles ;—W. Fairbairn, on the Strength of Materials considered in relation to the Construction of Iron Ships ;—Report of the Gun-Cotton Committee ;—A. F. Osler, on the Horary and Diurnal Variations in the Direction and Motion of the Air at Wrottesley, Liverpool, and Birmingham ;—B. W. Richardson, Second Report on the Physiological Action of certain of the Amyl Compounds ;—Report on further Researches in the Lingula-

flags of South Wales;—Report of the Lunar Committee for Mapping the Surface of the Moon;—Report on Standards of Electrical Resistance;—Report of the Committee appointed to communicate with the Russian Government respecting Magnetical Observations at Tiflis;—Appendix to Report on the Distribution of the Vertebrate Remains from the North Staffordshire Coal-field;—H. Woodward, First Report on the Structure and Classification of the Fossil Crustacea;—Prof. H. J. S. Smith, Report on the Theory of Numbers, Part VI.;—Report on the best means of providing for a Uniformity of Weights and Measures, with reference to the interests of Science:—A. G. Findlay, on the Bed of the Ocean;—Prof. A. W. Williamson, on the Composition of Gases evolved by the Bath Spring called King's Bath.

Together with the Transactions of the Sections, Prof. Phillips's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-SIXTH MEETING, at Nottingham, August 1866, *Published at* £1 4*s*.

CONTENTS:—Second Report on Kent's Cavern, Devonshire;—A. Matthiessen, Preliminary Report on the Chemical Nature of Cast Iron;—Report on Observations of Luminous Meteors;—W. S. Mitchell, Report on the Alum Bay Leaf-bed;—Report on the Resistance of Water to Floating and Immersed Bodies;—Dr. Norris, Report on Muscular Irritability;—Dr. Richardson, Report on the Physiological Action of certain compounds of Amyl and Ethyl;—H. Woodward, Second Report on the Structure and Classification of the Fossil Crustacea;—Second Report on the 'Menevian Group,' and the other Formations at St. David's, Pembrokeshire;—J. G. Jeffreys, Report on Dredging among the Hebrides;—Rev. A. M. Norman, Report on the Coasts of the Hebrides, Part II.;—J. Alder, Notices of some Invertebrata, in connexion with Mr. Jeffreys's Report;—G. S. Brady, Report on the *Ostracoda* dredged amongst the Hebrides;—Report on Dredging in the Moray Firth;—Report on the Transmission of Sound-Signals under Water;—Report of the Lunar Committee;—Report of the Rainfall Committee;—Report on the best means of providing for a Uniformity of Weights and Measures, with reference to the Interests of Science;—J. Glaisher, Account of Three Balloon Ascents;—Report on the Extinct Birds of the Mascarene Islands;—Report on the Penetration of Ironclad Ships by Steel Shot;—J. A. Wanklyn, Report on Isomerism among the Alcohols;—Report on Scientific Evidence in Courts of Law;—A. L. Adams, Second Report on Maltese Fossiliferous Caves, &c.

Together with the Transactions of the Sections, Mr. Grove's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-SEVENTH MEETING, at Dundee, September 1867, *Published at* £1 6*s*.

CONTENTS:—Report of the Committee for Mapping the Surface of the Moon;—Third Report on Kent's Cavern, Devonshire;—On the present State of the Manufacture of Iron in Great Britain;—Third Report on the Structure and Classification of the Fossil Crustacea;—Report on the Physiological Action of the Methyl Compounds;—Preliminary Report on the Exploration of the Plant-Beds of North Greenland;—Report of the Steamship Performance Committee;—On the Meteorology of Port Louis, in the Island of Mauritius;—On the Construction and Works of the Highland Railway;—Experimental Researches on the Mechanical Properties of Steel;—Report on the Marine Fauna and Flora of the South Coast of Devon and Cornwall;—Supplement to a Report on the Extinct Didine Birds of the Mascarene Islands;—Report on Observations of Luminous Meteors;—Fourth Report on Dredging among the Shetland Isles;—Preliminary Report on the Crustacea, &c., procured by the Shetland Dredging Committee in 1867;—Report on the Foraminifera obtained in the Shetland Seas;—Second Report of the Rainfall Committee;—Report on the best means of providing for a Uniformity of Weights and Measures, with reference to the interests of Science;—Report on Standards of Electrical Resistance.

Together with the Transactions of the Sections, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-EIGHTH MEETING, at Norwich, August 1868, *Published at* £1 5*s.*

CONTENTS:—Report of the Lunar Committee —Fourth Report on Kent's Cavern, Devonshire;—On Puddling Iron;—Fourth Report on the Structure and Classification of the Fossil Crustacea;—Report on British Fossil Corals;—Report on Spectroscopic Investigations of Animal Substances;—Report of Steamship Performance Committee;—Spectrum Analysis of the Heavenly Bodies;—On Stellar Spectrometry;—Report on the Physiological Action of the Methyl and allied Compounds;—Report on the Action of Mercury on the Biliary Secretion;—Last Report on Dredging among the Shetland Isles;—Reports on the Crustacea, &c., and on the Annelida and Foraminifera from the Shetland Dredgings;—Report on the Chemical Nature of Cast Iron, Part I.;—Interim Report on the Safety of Merchant Ships and their Passengers;—Report on Observations of Luminous Meteors;—Preliminary Report on Mineral Veins containing Organic Remains;—Report on the Desirability of Explorations between India and China;—Report of Rainfall Committee;—Report on Synthetical Researches on Organic Acids;—Report on Uniformity of Weights and Measures;—Report of the Committee on Tidal Observations;—Report of the Committee on Underground Temperature;—Changes of the Moon's Surface;—Report on Polyatomic Cyanides.

Together with the Transactions of the Sections, Dr. Hooker's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE THIRTY-NINTH MEETING, at Exeter, August 1869, *Published at* £1 2*s.*

CONTENTS:—Report on the Plant-beds of North Greenland;—Report on the existing knowledge on the Stability, Propulsion, and Seagoing qualities of Ships; —Report on Steam-boiler Explosions;—Preliminary Report on the Determination of the Gases existing in Solution in Well-waters;—The Pressure of Taxation on Real Property;—On the Chemical Reactions of Light discovered by Prof. Tyndall;—On Fossils obtained at Kiltorkan Quarry, co. Kilkenny;—Report of the Lunar Committee;—Report on the Chemical Nature of Cast Iron;—Report on the Marine Fauna and Flora of the South Coast of Devon and Cornwall;—Report on the Practicability of establishing a 'Close Time' for the Protection of Indigenous Animals;—Experimental Researches on the Mechanical Properties of Steel;—Second Report on British Fossil Corals;—Report of the Committee appointed to get cut and prepared Sections of Mountain-Limestone Corals for Photographing;—Report on the Rate of Increase of Underground Temperature;—Fifth Report on Kent's Cavern, Devonshire;—Report on the Connexion between Chemical Constitution and Physiological Action;—On Emission, Absorption, and Reflection of Obscure Heat;—Report on Observations of Luminous Meteors;—Report on Uniformity of Weights and Measures; —Report on the Treatment and Utilization of Sewage;—Supplement to Second Report of the Steamship-Performance Committee;—Report on Recent Progress in Elliptic and Hyperelliptic Functions;—Report on Mineral Veins in Carboniferous Limestone and their Organic Contents;—Notes on the Foraminifera of Mineral Veins and the Adjacent Strata;—Report of the Rainfall Committee;—Interim Report on the Laws of the Flow and Action of Water containing Solid Matter in Suspension;—Interim Report on Agricultural Machinery;—Report on the Physiological Action of Methyl and Allied Series;—On the Influence of Form considered in Relation to the Strength of Railway-axles and other portions of Machinery subjected to Rapid Alterations of Strain;—On the Penetration of Armour-plates with Long Shells of Large Capacity fired obliquely;—Report on Standards of Electrical Resistance.

Together with the Transactions of the Sections, Prof. Stokes's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTIETH MEETING, at Liverpool, September 1870, *Published at* 18*s.*

CONTENTS:—Report on Steam-boiler Explosions;—Report of the Committee on the Hæmatite Iron-ores of Great Britain and Ireland;—Report on the Sedimentary Deposits of the River Onny;—Report on the Chemical Nature of Cast Iron;—Report on the practicability of establishing a 'Close Time' for the protection of Indigenous Animals;—Report on Standards of Electrical Resistance;—Sixth Report on Kent's Cavern;—Third Report on Underground Temperature;—Second Report of the Committee appointed to get cut and prepared Sections of Mountain-Limestone Corals;—Second Report on the Stability, Propulsion, and Seagoing Qualities of Ships;—Report on Earthquakes in Scotland;—Report on the Treatment and Utilization of Sewage;—Report on Observations of Luminous Meteors, 1869-70;—Report on Recent Progress in Elliptic and Hyperelliptic Functions;—Report on Tidal Observations;—On a new Steam-power Meter;—Report on the Action of the Methyl and Allied Series;—Report of the Rainfall Committee;—Report on the Heat generated in the Blood in the Process of Arterialization;—Report on the best means of providing for Uniformity of Weights and Measures.

Together with the Transactions of the Sections, Prof. Huxley's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-FIRST MEETING, at Edinburgh, August 1871, *Published at* 16*s.*

CONTENTS:—Seventh Report on Kent's Cavern;—Fourth Report on Underground Temperature;—Report on Observations of Luminous Meteors, 1870–71;—Fifth Report on the Structure and Classification of the Fossil Crustacea;—Report of the Committee appointed for the purpose of urging on Her Majesty's Government the expediency of arranging and tabulating the results of the approaching Census in the three several parts of the United Kingdom in such a manner as to admit of ready and effective comparison;—Report of the Committee appointed for the purpose of Superintending the Publication of Abstracts of Chemical Papers;—Report of the Committee for discussing Observations of Lunar Objects suspected of change;—Second Provisional Report on the Thermal Conductivity of Metals;—Report on the Rainfall of the British Isles;—Third Report on the British Fossil Corals;—Report on the Heat generated in the Blood during the Process of Arterialization;—Report of the Committee appointed to consider the subject of Physiological Experimentation;—Report on the Physiological Action of Organic Chemical Compounds;—Report of the Committee appointed to get cut and prepared Sections of Mountain-Limestone Corals;—Second Report on Steam-Boiler Explosions;—Report on the Treatment and Utilization of Sewage;—Report on promoting the Foundation of Zoological Stations in different parts of the World;—Preliminary Report on the Thermal Equivalents of the Oxides of Chlorine;—Report on the practicability of establishing a 'Close Time' for the protection of Indigenous Animals;—Report on Earthquakes in Scotland;—Report on the best means of providing for a Uniformity of Weights and Measures;—Report on Tidal Observations.

Together with the Transactions of the Sections, Sir William Thomson's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-SECOND MEETING, at Brighton, August 1872, *Published at* £1 4*s.*

CONTENTS:—Report on the Gaussian Constants for the Year 1829;—Second Supplementary Report on the Extinct Birds of the Mascarene Islands;—Report of the Committee for Superintending the Monthly Reports of the Progress of Chemistry;—Report of the Committee on the best means of providing for a Uniformity of Weights and Measures;—Eighth Report on Kent's Cavern;—Report on promoting the Foundation of Zoological Stations in different parts of the World;—Fourth Report

on the Fauna of South Devon;—Preliminary Report of the Committee appointed to Construct and Print Catalogues of Spectral Rays arranged upon a Scale of Wave-numbers;—Third Report on Steam-Boiler Explosions;—Report on Observations of Luminous Meteors, 1871–72;—Experiments on the Surface-friction experienced by a Plane moving through Water;—Report of the Committee on the Antagonism between the Action of Active Substances;—Fifth Report on Underground Temperature;—Preliminary Report of the Committee on Siemens's Electrical-Resistance Pyrometer:—Fourth Report on the Treatment and Utilization of Sewage;—Interim Report of the Committee on Instruments for Measuring the Speed of Ships and Currents;—Report on the Rainfall of the British Isles;—Report of the Committee on a Geographical Exploration of the Country of Moab;—Sur l'élimination des Fonctions Arbitraires;—Report on the Discovery of Fossils in certain remote parts of the North-western Highlands;—Report of the Committee on Earthquakes in Scotland;—Fourth Report on Carboniferous-Limestone Corals;—Report of the Committee to consider the mode in which new Inventions and Claims for Reward in respect of adopted Inventions are examined and dealt with by the different Departments of Government;—Report of the Committee for discussing Observations of Lunar Objects suspected of change;—Report on the Mollusca of Europe;—Report of the Committee for investigating the Chemical Constitution and Optical Properties of Essential Oils;—Report on the practicability of establishing a 'Close Time' for the preservation of Indigenous Animals;—Sixth Report on the Structure and Classification of Fossil Crustacea;—Report of the Committee appointed to organize an Expedition for observing the Solar Eclipse of Dec. 12, 1871;—Preliminary Report of a Committee on Terato-embryological Inquiries;—Report on Recent Progress in Elliptic and Hyperelliptic Functions;—Report on Tidal Observations;—On the Brighton Waterworks;—On Amsler's Planimeter.

Together with the Transactions of the Sections, Dr. Carpenter's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-THIRD MEETING, at Bradford, September 1873, *Published at £1 5s.*

CONTENTS:—Report of the Committee on Mathematical Tables;—Observations on the Application of Machinery to the Cutting of Coal in Mines;—Concluding Report on the Maltese Fossil Elephants;—Report of the Committee for ascertaining the Existence in different parts of the United Kingdom of any Erratic Blocks or Boulders;—Fourth Report on Earthquakes in Scotland;—Ninth Report on Kent's Cavern;—On the Flint and Chert Implements found in Kent's Cavern;—Report of the Committee for Investigating the Chemical Constitution and Optical Properties of Essential Oils;—Report of Inquiry into the Method of making Gold-assays; —Fifth Report on the Selection and Nomenclature of Dynamical and Electrical Units;—Report of the Committee on the Labyrinthodonts of the Coal-measures;—Report of the Committee appointed to construct and print Catalogues of Spectral Rays;—Report of the Committee appointed to explore the Settle Caves;—Sixth Report on Underground Temperature;—Report on the Rainfall of the British Isles;—Seventh Report on Researches in Fossil Crustacea;—Report on Recent Progress in Elliptic and Hyperelliptic Functions;—Report on the desirability of establishing a 'Close Time' for the preservation of Indigenous Animals;—Report on Luminous Meteors; —On the Visibility of the Dark Side of Venus;—Report of the Committee for the Foundation of Zoological Stations in different parts of the World;—Second Report of the Committee for collecting Fossils from North-western Scotland;—Fifth Report on the Treatment and Utilization of Sewage;—Report of the Committee on Monthly Reports of the Progress of Chemistry;—On the Bradford Waterworks;—Report on the possibility of Improving the Methods of Instruction in Elementary Geometry; —Interim Report of the Committee on Instruments for Measuring the Speed of Ships, &c.;—Report of the Committee for Determinating High Temperatures by means of the Refrangibility of Light evolved by Fluid or Solid Substances;—On a periodicity of Cyclones and Rainfall in connexion with Sun-spot Periodicity;—Fifth Report on the Structure of Carboniferous-Limestone Corals;—Report of the Committee on preparing and publishing brief forms of Instructions for Travellers, Ethnologists, &c.;—Preliminary Note from the Committee on the Influence of Forests

on the Rainfall;—Report of the Sub-Wealden Exploration Committee;—Report of the Committee on Machinery for obtaining a Record of the Roughness of the Sea and Measurement of Waves near shore;—Report on Science Lectures and Organization;—Second Report on Science Lectures and Organization.

Together with the Transactions of the Sections, Prof. A. W. Williamson's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS of the FORTY-FOURTH MEETING, at Belfast, August 1874, *Published at £1 5s.*

Contents:—Tenth Report on Kent's Cavern;—Report for investigating the Chemical Constitution and Optical Properties of Essential Oils;—Second Report of the Sub-Wealden Exploration Committee;—On the Recent Progress and Present State of Systematic Botany;—Report of the Committee for investigating the Nature of Intestinal Secretion;—Report of the Committee on the Teaching of Physics in Schools;—Preliminary Report for investigating Isomeric Cresols and their Derivatives;—Third Report of the Committee for collecting Fossils from localities in North-western Scotland;—Report on the Rainfall of the British Isles;—On the Belfast Harbour;—Report of Inquiry into the Method of making Gold-assays;—Report of a Committee on Experiments to determine the Thermal Conductivities of certain Rocks;—Second Report on the Exploration of the Settle Caves;—On the Industrial uses of the Upper Bann River;—Report of the Committee on the Structure and Classification of the Labyrinthodonts;—Second Report of the Committee for recording the position, height above the sea, lithological characters, size, and origin of the Erratic Blocks of England and Wales, &c.;—Sixth Report on the Treatment and Utilization of Sewage;—Report on the Anthropological Notes and Queries for the use of Travellers;—On Cyclone and Rainfall Periodicities;—Fifth Report on Earthquakes in Scotland;—Report of the Committee appointed to prepare and print Tables of Wave-numbers;—Report of the Committee for testing the new Pyrometer of Mr. Siemens;—Report to the Lords Commissioners of the Admiralty on Experiments for the Determination of the Frictional Resistance of Water on a Surface &c.;—Second Report for the Selection and Nomenclature of Dynamical and Electrical Units;—On Instruments for measuring the Speed of Ships;—Report of the Committee on the possibility of establishing a 'Close Time' for the Protection of Indigenous Animals;—Report of the Committee to inquire into the economic effects of Combinations of Labourers and Capitalists;—Preliminary Report on Dredging on the Coasts of Durham and North Yorkshire;—Report on Luminous Meteors;—Report on the best means of providing for a Uniformity of Weights and Measures.

Together with the Transactions of the Sections, Prof. John Tyndall's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS of the FORTY-FIFTH MEETING, at Bristol, August 1875, *Published at £1 5s.*

Contents:—Eleventh Report on Kent's Cavern;—Seventh Report on Underground Temperature;—Report on the Zoological Station at Naples;—Report of a Committee appointed to inquire into the Methods employed in the Estimation of Potash and Phosphoric Acid in Commercial Products;—Report on the present state of our Knowledge of the Crustacea;—Second Report on the Thermal Conductivities of certain Rocks;—Preliminary Report of the Committee for extending the Observations on the Specific Volumes of Liquids;—Sixth Report on Earthquakes in Scotland;—Seventh Report on the Treatment and Utilization of Sewage;—Report of the Committee for furthering the Palestine Explorations;—Third Report of the Committee for recording the position, height above the sea, lithological characters, size, and origin of the Erratic Blocks of England and Wales, &c.;—Report of the Rainfall Committee;—Report of the Committee for investigating Isomeric Cresols and their Derivatives;—Report of the Committee for investigating the Circulation of the Underground Waters in the New Red Sandstone and Permian Formations of England;—On the Steering of Screw-Steamers;—Second Report of

the Committee on Combinations of Capital and Labour;—Report on the Method of making Gold-assays;—Eighth Report on Underground Temperature;—Tides in the River Mersey;—Sixth Report of the Committee on the Structure of Carboniferous Corals;—Report of the Committee appointed to explore the Settle Caves;—On the River Avon (Bristol), its Drainage-Area, &c.;—Report of the Committee on the possibility of establishing a 'Close Time' for the Protection of Indigenous Animals;—Report of the Committee appointed to superintend the Publication of the Monthly Reports of the Progress of Chemistry;—Report on Dredging off the Coasts of Durham and North Yorkshire in 1874;—Report on Luminous Meteors;—On the Analytical Forms called Trees;—Report of the Committee on Mathematical Tables;—Report of the Committee on Mathematical Notation and Printing;—Second Report of the Committee for investigating Intestinal Secretion;—Third Report of the Sub-Wealden Exploration Committee.

Together with the Transactions of the Sections, Sir John Hawkshaw's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-SIXTH MEETING, at Glasgow, September 1876, *Published at* £1 5*s*.

CONTENTS:—Twelfth Report on Kent's Cavern;—Report on Improving the Methods of Instruction in Elementary Geometry;—Results of a Comparison of the British-Association Units of Electrical Resistance;—Third Report on the Thermal Conductivities of certain Rocks;—Report of the Committee on the practicability of adopting a Common Measure of Value in the Assessment of Direct Taxation;—Report of the Committee for testing experimentally Ohm's Law;—Report of the Committee on the possibility of establishing a 'Close Time' for the Protection of Indigenous Animals;—Report of the Committee on the Effect of Propellers on the Steering of Vessels;—On the Investigation of the Steering Qualities of Ships;—Seventh Report on Earthquakes in Scotland;—Report on the present state of our Knowledge of the Crustacea;—Second Report of the Committee for investigating the Circulation of the Underground Waters in the New Red Sandstone and Permian Formations of England;—Fourth Report of the Committee on the Erratic Blocks of England and Wales, &c.;—Fourth Report of the Committee on the Exploration of the Settle Caves (Victoria Cave);—Report on Observations of Luminous Meteors, 1875–76;—Report on the Rainfall of the British Isles, 1875–76;—Ninth Report on Underground Temperature;—Nitrous Oxide in the Gaseous and Liquid States;—Eighth Report on the Treatment and Utilization of Sewage;—Improved Investigations on the Flow of Water through Orifices, with Objections to the modes of treatment commonly adopted;—Report of the Anthropometric Committee;—On Cyclone and Rainfall Periodicities in connexion with the Sun-spot Periodicity;—Report of the Committee for determining the Mechanical Equivalent of Heat;—Report of the Committee on Tidal Observations;—Third Report of the Committee on the Conditions of Intestinal Secretion and Movement;—Report of the Committee for collecting and suggesting subjects for Chemical Research.

Together with the Transactions of the Sections, Dr. T. Andrews's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-SEVENTH MEETING, at Plymouth, August 1877, *Published at* £1 4*s*.

CONTENTS:—Thirteenth Report on Kent's Cavern;—Second and Third Reports on the Methods employed in the estimation of Potash and Phosphoric Acid in Commercial Products;—Report on the present state of our Knowledge of the Crustacea (Part III.);—Third Report on the Circulation of the Underground Waters in the New Red Sandstone and Permian Formations of England;—Fifth Report on the Erratic Blocks of England, Wales, and Ireland;—Fourth Report on the Thermal Conductivities of certain Rocks;—Report on Observations of Luminous Meteors, 1876–77;—Tenth Report on Underground Temperature;—Report on the Effect of Propellers on the Steering of Vessels;—Report on the possibility of establishing a 'Close Time' for the Protection of Indigenous Animals;—Report on some Double Compounds of

Nickel and Cobalt;—Fifth Report on the Exploration of the Settle Caves (Victoria Cave);—Report on the Datum Level of the Ordnance Survey of Great Britain;—Report on the Zoological Station at Naples;—Report of the Anthropometric Committee;—Report on the Conditions under which Liquid Carbonic Acid exists in Rocks and Minerals.

Together with the Transactions of the Sections, Prof. Allen Thomson's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-EIGHTH MEETING, at Dublin, August 1878, *Published at* £1 4*s*.

CONTENTS:—Catalogue of the Oscillation-Frequencies of Solar Rays;—Report on Mr. Babbage's Analytical Machine;—Third Report of the Committee for determining the Mechanical Equivalent of Heat;—Report of the Committee for arranging for the taking of certain Observations in India, and Observations on Atmospheric Electricity at Madeira;—Report on the commencement of Secular Experiments upon the Elasticity of Wires;—Report on the Chemistry of some of the lesser-known Alkaloids, especially Veratria and Bebeerine;—Report on the best means for the Development of Light from Coal-Gas;—Fourteenth Report on Kent's Cavern;—Report on the Fossils in the North-west Highlands of Scotland;—Fifth Report on the Thermal Conductivities of certain Rocks;—Report on the possibility of establishing a 'Close Time' for the Protection of Indigenous Animals;—Report on the occupation of a Table at the Zoological Station at Naples;—Report of the Anthropometric Committee;—Report on Patent Legislation;—Report on the Use of Steel for Structural Purposes;—Report on the Geographical Distribution of the Chiroptera;—Recent Improvements in the Port of Dublin;—Report on Mathematical Tables;—Eleventh Report on Underground Temperature;—Report on the Exploration of the Fermanagh Caves;—Sixth Report on the Erratic Blocks of England, Wales, and Ireland;—Report on the present state of our Knowledge of the Crustacea (Part IV.);—Report on two Caves in the neighbourhood of Tenby;—Report on the Stationary Tides in the English Channel and in the North Sea, &c.;—Second Report on the Datum-level of the Ordnance Survey of Great Britain;—Report on instruments for measuring the Speed of Ships;—Report of Investigations into a Common Measure of Value in Direct Taxation;—Report on Sunspots and Rainfall;—Report on Observations of Luminous Meteors;—Sixth Report on the Exploration of the Settle Caves (Victoria Cave);—Report on the Kentish Boring Exploration;—Fourth Report on the Circulation of Underground Waters in the Jurassic, New Red Sandstone, and Permian Formations, with an Appendix on the Filtration of Water through Triassic Sandstone;—Report on the Effect of Propellers on the Steering of Vessels.

Together with the Transactions of the Sections, Mr. Spottiswoode's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FORTY-NINTH MEETING, at Sheffield, August 1879, *Published at* £1 4*s*.

CONTENTS:—Report on the commencement of Secular Experiments upon the Elasticity of Wires;—Fourth Report of the Committee for determining the Mechanical Equivalent of Heat;—Report of the Committee for endeavouring to procure reports on the Progress of the Chief Branches of Mathematics and Physics;—Twelfth Report on Underground Temperature;—Report on Mathematical Tables;—Sixth Report on the Thermal Conductivities of certain Rocks;—Report on Observations of Atmospheric Electricity at Madeira;—Report on the Calculation of Tables of the Fundamental Invariants of Algebraic Forms;—Report on the Calculation of Sun-Heat Coefficients;—Second Report on the Stationary Tides in the English Channel and in the North Sea, &c.;—Report on Observations of Luminous Meteors;—Report on the question of Improvements in Astronomical Clocks;—Report of the Committee for improving an Instrument for detecting the presence of Fire-damp in Mines;—Report on the Chemistry of some of the lesser-known Alkaloids, especially Veratria

and Beeberine;—Seventh Report on the Erratic Blocks of England, Wales, and Ireland;—Fifteenth Report on Kent's Cavern;—Report on certain Caves in Borneo;—Fifth Report on the Circulation of Underground Waters in the Jurassic, Red Sandstone, and Permian Formations of England;—Report on the Tertiary (Miocene) Flora, &c., of the Basalt of the North of Ireland;—Report on the possibility of Establishing a 'Close Time' for the Protection of Indigenous Animals;—Report on the Marine Zoology of Devon and Cornwall;—Report on the Occupation of a Table at the Zoological Station at Naples;—Report on Excavations at Portstewart and elsewhere in the North of Ireland;—Report of the Anthropometric Committee;—Report on the Investigation of the Natural History of Socotra;—Report on Instruments for measuring the Speed of Ships;—Third Report on the Datum-level of the Ordnance Survey of Great Britain;—Second Report on Patent Legislation;—On Self-acting Intermittent Siphons and the conditions which determine the commencement of their Action;—On some further Evidence as to the Range of the Palæozoic Rocks beneath the South-east of England;—Hydrography, Past and Present.

Together with the Transactions of the Sections, Prof. Allman's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FIFTIETH MEETING, at Swansea, August and September 1880, *Published at £1 4s.*

CONTENTS:—Report on the Measurement of the Lunar Disturbance of Gravity;—Thirteenth Report on Underground Temperature;—Report of the Committee for devising and constructing an improved form of High Insulation Key for Electrometer Work;—Report on Mathematical Tables;—Report on the Calculation of Tables of the Fundamental Invariants of Algebraic Forms;—Report on Observations of Luminous Meteors;—Report on the question of Improvements in Astronomical Clocks;—Report on the commencement of Secular Experiments on the Elasticity of Wires;—Sixteenth and concluding Report on Kent's Cavern;—Report on the mode of reproduction of certain species of Ichthyosaurus from the Lias of England and Würtemburg;—Report on the Carboniferous Polyzoa;—Report on the 'Geological Record';—Sixth Report on the Circulation of the Underground Waters in the Permian, New Red Sandstone, and Jurassic Formations of England, and the Quantity and Character of the Water supplied to towns and districts from these formations;—Second Report on the Tertiary (Miocene) Flora, &c., of the Basalt of the North of Ireland;—Eighth Report on the Erratic Blocks of England, Wales, and Ireland;—Report on an Investigation for the purpose of fixing a Standard of White Light;—Report of the Anthropometric Committee;—Report on the Influence of Bodily Exercise on the Elimination of Nitrogen;—Second Report on the Marine Zoology of South Devon;—Report on the Occupation of a Table at the Zoological Station at Naples;—Report on accessions to our knowledge of the Chiroptera during the past two years (1878–80);—Preliminary Report on the accurate measurement of the specific inductive capacity of a good Sprengel Vacuum, and the specific resistance of gases at different pressures;—Comparison of Curves of the Declination Magnetographs at Kew, Stonyhurst, Coimbra, Lisbon, Vienna, and St. Petersburg;—First Report on the Caves of the South of Ireland;—Report on the Investigation of the Natural History of Socotra;—Report on the German and other systems of teaching the Deaf to speak;—Report of the Committee for considering whether it is important that H.M. Inspectors of Elementary Schools should be appointed with reference to their ability for examining in the scientific specific subjects of the Code in addition to other matters;—On the Anthracite Coal and Coalfield of South Wales;—Report on the present state of our knowledge of Crustacea (Part V.);—Report on the best means for the Development of Light from Coal-gas of different qualities (Part II.);—Report on Palæontological and Zoological Researches in Mexico;—Report on the possibility of establishing a 'Close Time' for Indigenous Animals;—Report on the present state of our knowledge of Spectrum Analysis;—Report on Patent Legislation;—Preliminary Report on the present Appropriation of Wages, &c.;—Report on the present state of knowledge of the application of Quadratures and Interpolation to Actual Data;—The French Deep-sea Exploration in the Bay of Biscay;—Third Report on the Stationary Tides in the English Channel and in the North Sea, &c.;—List of

Works on the Geology, Mineralogy, and Palæontology of Wales (to the end of 1873);—On the recent Revival in Trade.

Together with the Transactions of the Sections, Dr. A. C. Ramsay's Address, and Recommendations of the Association and its Committees.

PROCEEDINGS OF THE FIFTY-FIRST MEETING, at York, August and September 1881, *Published at £1 4s.*

CONTENTS:—Report on the Calculation of Tables of the Fundamental Invariants of Algebraic Forms;—Report on Recent Progress in Hydrodynamics (Part I.);—Report on Meteoric Dust;—Second Report on the Calculation of Sun-heat Coefficients;—Fourteenth Report on Underground Temperature;—Report on the Measurement of the Lunar Disturbance of Gravity;—Second Report on an Investigation for the purpose of fixing a Standard of White Light;—Final Report on the Thermal Conductivities of certain Rocks;—Report on the manner in which Rudimentary Science should be taught, and how Examinations should be held therein, in Elementary Schools;—Third Report on the Tertiary Flora of the North of Ireland;—Report on the Method of Determining the Specific Refraction of Solids from their Solutions;—Fourth Report on the Stationary Tides in the English Channel and in the North Sea, &c.;—Second Report on Fossil Polyzoa;—Report on the Maintenance of the Scottish Zoological Station;—Report on the Occupation of a Table at the Zoological Station at Naples;—Report on the Migration of Birds;—Report on the Natural History of Socotra;—Report on the Natural History of Timor-laut;—Report on the Marine Fauna of the Southern Coast of Devon and Cornwall;—Report on the Earthquake Phenomena of Japan;—Ninth Report on the Erratic Blocks of England, Wales, and Ireland;—Second Report on the Caves of the South of Ireland;—Report on Patent Legislation;—Report of the Anthropometric Committee;—Report on the Appropriation of Wages, &c.;—Report on Observations of Luminous Meteors;—Report on Mathematical Tables;—Seventh Report on the Circulation of Underground Waters in the Jurassic, New Red Sandstone, and Permian Formations of England, and the Quality and Quantity of the Water supplied to Towns and Districts from these Formations;—Report on the present state of our Knowledge of Spectrum Analysis;—Interim Report of the Committee for constructing and issuing practical Standards for use in Electrical Measurements;—On some new Theorems on Curves of Double Curvature;—Observations of Atmospheric Electricity at the Kew Observatory during 1880;—On the Arrestation of Infusorial Life by Solar Light;—On the Effects of Oceanic Currents upon Climates;—On Magnetic Disturbances and Earth Currents;—On some Applications of Electric Energy to Horticultural and Agricultural purposes;—On the Pressure of Wind upon a Fixed Plane Surface;—On the Island of Socotra;—On some of the Developments of Mechanical Engineering during the last Half-Century.

Together with the Transactions of the Sections, Sir John Lubbock's Address, and Recommendations of the Association and its Committees.

REPORT OF THE FIFTY-SECOND MEETING, at Southampton, August 1882, *Published at £1 4s.*

CONTENTS:—Report on the Calculation of Tables of Fundamental Invariants of Binary Quantics;—Report (provisional) of the Committee for co-operating with the Meteorological Society of the Mauritius in their proposed publication of Daily Synoptic Charts of the Indian Ocean from the year 1861;—Report of the Committee appointed for fixing a Standard of White Light;—Report on Recent Progress in Hydrodynamics (Part II.);—Report of the Committee for constructing and issuing practical Standards for use in Electrical Measurements;—Fifteenth Report on Underground Temperature, with Summary of the Results contained in the Fifteen Reports of the Underground Temperature Committee;—Report on Meteoric Dust;—Second Report on the Measurement of the Lunar Disturbance of Gravity;—Report on the present state of our Knowledge of Spectrum Analysis;—Report on the Investigation by means of Photography of the Ultra-Violet Spark Spectra emitted by Metallic Elements, and their combinations under varying conditions;—Report of the Committee for preparing a new Series of Tables of Wave-lengths of the Spectra of the Elements;—Report on the Methods employed in the Calibration of Mercurial Ther-

mometers;—Second Report on the Earthquake Phenomena of Japan;—Eighth Report on the Circulation of the Underground Waters in the Permeable Formations of England, and the Quality and Quantity of the Water supplied to various Towns and Districts from these Formations;—Report on the Conditions under which ordinary Sedimentary Materials may be converted into Metamorphic Rocks;—Report on Explorations in Caves of Carboniferous Limestone in the South of Ireland;—Report on the Preparation of an International Geological Map of Europe;—Tenth Report on the Erratic Blocks of England, Wales, and Ireland;—Report on Fossil Polyzoa (Jurassic Species—British Area only);—Preliminary Report on the Flora of the 'Halifax Hard Bed,' Lower Coal Measures;—Report on the Influence of Bodily Exercise on the Elimination of Nitrogen;—Report of the Committee appointed for obtaining Photographs of the Typical Races in the British Isles;—Preliminary Report on the Ancient Earthwork in Epping Forest known as the Loughton Camp;—Second Report on the Natural History of Timor-laut;—Report of the Committee for carrying out the recommendations of the Anthropometric Committee of 1880, especially as regards the anthropometry of children and of females, and the more complete discussion of the collected facts;—Report on the Natural History of Socotra and the adjacent Highlands of Arabia and Somali Land;—Report on the Maintenance of the Scottish Zoological Station;—Report on the Migration of Birds;—Report on the Occupation of a Table at the Zoological Station at Naples;—Report on the Survey of Eastern Palestine;—Final Report on the Appropriation of Wages, &c.;—Report on the workings of the revised New Code, and of other legislation affecting the teaching of Science in Elementary Schools;—Report on Patent Legislation;—Report of the Committee for determining a Gauge for the manufacture of various small Screws;—Report on the best means of ascertaining the Effective Wind Pressure to which buildings and structures are exposed;—On the Boiling Points and Vapour Tension of Mercury, of Sulphur, and of some Compounds of Carbon, determined by means of the Hydrogen Thermometer;—On the Method of Harmonic Analysis used in deducing the Numerical Values of the Tides of long period, and on a Misprint in the Tidal Report for 1872;—List of Works on the Geology and Palæontology of Oxfordshire, of Berkshire, and of Buckinghamshire;—Notes on the oldest Records of the Sea-Route to China from Western Asia;—The Deserts of Africa and Asia;—State of Crime in England, Scotland, and Ireland in 1880;—On the Treatment of Steel for the Construction of Ordnance, and other purposes;—The Channel Tunnel;—The Forth Bridge.

Together with the Transactions of the Sections, Dr. C. W. Siemens's Address, and Recommendations of the Association and its Committees.

REPORT OF THE FIFTY-THIRD MEETING, at Southport, September 1883, *Published at £1 4s.*

CONTENTS:—Report of the Committee for constructing and issuing practical Standards for use in Electrical Measurements;—Sixteenth Report on Underground Temperature;—Report on the best Experimental Methods that can be used in observing Total Solar Eclipses;—Report on the Harmonic Analysis of Tidal Observations;—Report of the Committee for co-operating with the Meteorological Society of the Mauritius in their proposed publication of Daily Synoptic Charts of the Indian Ocean from the year 1861;—Report on Mathematical Tables;—Report of the Committee for co-operating with the Scottish Meteorological Society in making Meteorological Observations on Ben Nevis;—Report on Meteoric Dust;—Report of the Committee appointed for fixing a Standard of White Light;—Report on Chemical Nomenclature;—Report on the investigation by means of Photography of the Ultra-Violet Spark Spectra emitted by Metallic Elements, and their combinations under varying conditions;—Report on Isomeric Naphthalene Derivatives;—Report on Explorations in Caves in the Carboniferous Limestone in the South of Ireland;—Report on the Exploration of Raygill Fissure, Yorkshire;—Eleventh Report on the Erratic Blocks of England, Wales, and Ireland;—Ninth Report on the Circulation of the Underground Waters in the Permeable Formations of England, and the Quality and Quantity of the Water supplied to various Towns and Districts from these Formations;—Report on the Fossil Plants of Halifax;—Fourth Report on Fossil Polyzoa;—Fourth Report on the Tertiary Flora of the North of Ireland;—Report on the Earthquake Phenomena of Japan;—Report on the Fossil Phyllopoda of the

Palæozoic Rocks;—Third Report on the Natural History of Timor Laut;—Report on the Natural History of Socotra and the adjacent Highlands of Arabia and Somali Land;—Report on the Exploration of Kilima-njaro and the adjoining mountains of Eastern Equatorial Africa;—Report on the Migration of Birds;—Report on the Maintenance of the Scottish Zoological Station;—Report on the Occupation of a Table at the Zoological Station at Naples;—Report on the Influence of Bodily Exercise on the Elimination of Nitrogen;—Report on the Ancient Earthwork in Epping Forest, known as the 'Loughton' or 'Cowper's' Camp;—Final Report of the Anthropometric Committee;—Report of the Committee for defining the Facial Characteristics of the Races and Principal Crosses in the British Isles, and obtaining Illustrative Photographs;—Report on the Survey of Eastern Palestine;—Report on the workings of the proposed revised New Code, and of other legislation affecting the teaching of Science in Elementary Schools;—Report on Patent Legislation;—Report of the Committee for determining a Gauge for the manufacture of various small Screws;—Report of the 'Local Scientific Societies' Committee;—On some results of photographing the Solar Corona without an Eclipse;—On Lamé's Differential Equation;—Recent Changes in the Distribution of Wealth in relation to the Incomes of the Labouring Classes;—On the Mersey Tunnel;—On Manganese Bronze;—Nest Gearing.

Together with the Transactions of the Sections, Professor Cayley's Address, and Recommendations of the Association and its Committees.

REPORT OF THE FIFTY-FOURTH MEETING, at Montreal, August and September, 1884, *Published at 1l. 4s.*

CONTENTS:—Report of the Committee for considering and advising on the best means for facilitating the adoption of the Metric System of Weights and Measures in Great Britain;—Report of the Committee for considering the best methods of recording the direct intensity of Solar Radiation;—Report of the Committee for constructing and issuing practical Standards for use in Electrical Measurements;—Report of the Committee for co-operating with the Meteorological Society of the Mauritius, in their proposed publication of Daily Synoptic Charts of the Indian Ocean from the year 1861;—Second Report on the Harmonic Analysis of Tidal Observations;—Report of the Committee for co-operating with Mr. E. J. Lowe in his project of establishing a Meteorological Observatory near Chepstow on a permanent and scientific basis;—Report of the Committee for co-operating with the Directors of the Ben Nevis Observatory in making Meteorological Observations on Ben Nevis;—Report of the Committee for reducing and tabulating the Tidal Observations in the English Channel, made with the Dover Tide-gauge, and for connecting them with Observations made on the French Coast;—Fourth Report on Meteoric Dust;—Second Report on Chemical Nomenclature;—Report on Isomeric Naphthalene Derivatives;—Second Report on the Fossil Phyllopoda of the Palæozoic Rocks;—Tenth Report on the Circulation of Underground Waters in the Permeable Formations of England and Wales, and the Quantity and Character of the Water supplied to various Towns and Districts from these Formations;—Fifth and last Report on Fossil Polyzoa;—Twelfth Report on the Erratic Blocks of England, Wales, and Ireland;—Report upon the National Geological Surveys of Europe;—Report on the Rate of Erosion of the Sea-coasts of England and Wales, and the Influence of the Artificial Abstraction of Shingle or other material in that action;—Report on the Exploration of the Raygill Fissure in Lothersdale, Yorkshire;—Fourth Report on the Earthquake Phenomena of Japan;—Report on the occupation of a Table at the Zoological Station at Naples;—Fourth Report on the Natural History of Timor Laut;—Report on the Influence of Bodily Exercise on the Elimination of Nitrogen;—Report on the Migration of Birds;—Report on the Preparation of a Bibliography of certain groups of Invertebrata;—Report on the Exploration of Kilima-njaro, and the adjoining mountains of Eastern Equatorial Africa;—Report on the Survey of Eastern Palestine;—Report of the Committee for defraying the expenses of completing the Preparation of the final Report of the Anthropometric Committee;—Report on the teaching of Science in Elementary Schools;—Report of the Committee for determining a Gauge for the manufacture of the various small Screws used in Telegraphic and Electrical Apparatus, in Clockwork, and for other analogous purposes;—Report on Patent Legislation;—Report of the Committee for defining the Facial Charac-

teristics of the Races and Principal Crosses in the British Isles, and obtaining Illustrative Photographs with a view to their publication;—Report on the present state of our knowledge of Spectrum Analysis;—Report of the Committee for preparing a new series of Wave-length Tables of the Spectra of the Elements;—On the Connection between Sun-spots and Terrestrial Phenomena;—On the Seat of the Electromotive Forces in the Voltaic Cell;—On the Archæan Rocks of Great Britain;—On the Concordance of the Mollusca inhabiting both sides of the North Atlantic and the intermediate Seas;—On the Characteristics of the North American Flora; On the Theory of the Steam Engine;—Improvements in Coast Signals, with Supplementary Remarks on the New Eddystone Lighthouse;—On American Permanent Way.

Together with the Transactions of the Sections, Lord Rayleigh's Address, and Recommendations of the Association and its Committees.

BRITISH ASSOCIATION

FOR

THE ADVANCEMENT OF SCIENCE.

LIST

OF

OFFICERS, COUNCIL, AND MEMBERS,

CORRECTED TO APRIL 6, 1886.

[*Office of the Association:—22 Albemarle Street, London, W.*]

OFFICERS AND COUNCIL, 1885-86.

PRESIDENT.

The Right Hon. Sir LYON PLAYFAIR, K.C.B., M.P., Ph.D., LL.D., F.R.S. L. & E., F.C.S.

VICE-PRESIDENTS.

His Grace the DUKE OF RICHMOND AND GORDON, K.G., D.C.L., Chancellor of the University of Aberdeen.
The Right Hon. the EARL OF ABERDEEN, LL.D., Lord-Lieutenant of Aberdeenshire.
The Right Hon. the EARL OF CRAWFORD AND BALCARRES, M.A., LL.D., F.R.S., F.R.A.S.
JAMES MATTHEWS, Esq., Lord Provost of the City of Aberdeen.
Professor Sir WILLIAM THOMSON, M.A., LL.D., F.R.S. L. & E., F.R.A.S.
ALEXANDER BAIN, Esq., M.A., LL.D., Rector of the University of Aberdeen.
Professor W. H. FLOWER, LL.D., F.R.S., F.L.S., F.G.S., Pres. Z.S., Director of the Natural History Museum, London.
Professor JOHN STRUTHERS, M.D., LL.D.

PRESIDENT ELECT.

Sir WILLIAM DAWSON, C.M.G., M.A., LL.D., F.R.S., F.G.S., Principal of McGill College, Montreal, Canada.

VICE-PRESIDENTS ELECT.

The Right Hon. the EARL OF BRADFORD, Lord-Lieutenant of Shropshire.
The Right Hon. LORD LEIGH, D.C.L., Lord-Lieutenant of Warwickshire.
The Right Hon. LORD NORTON, K.C.M.G.
The Right Hon. LORD WROTTESLEY, Lord-Lieutenant of Staffordshire.
The Right Rev. the LORD BISHOP OF WORCESTER, D.D.
THOMAS MARTINEAU, Esq., Mayor of Birmingham.
Professor G. G. STOKES, M.A., D.C.L., LL.D., Pres. R.S.
Professor W. A. TILDEN, D.Sc., F.R.S., F.C.S.
Rev. A. R. VARDY, M.A.
Rev. H. W. WATSON, D.Sc., F.R.S.

LOCAL SECRETARIES FOR THE MEETING AT BIRMINGHAM.

Rev. H. W. CROSSKEY, LL.D., F.G.S. | J. BARHAM CARSLAKE, Esq. | CHARLES J. HART, Esq.

LOCAL TREASURER FOR THE MEETING AT BIRMINGHAM.

J. D. GOODMAN, Esq.

ORDINARY MEMBERS OF THE COUNCIL.

ABNEY, Capt. W. DE W., F.R.S.
BALL, Professor R. S., F.R.S.
BATEMAN, J. F. LA TROBE, Esq., F.R.S.
BLANFORD, W. T. Esq., F.R.S.
BRAMWELL, Sir F. J., F.R.S.
CROOKES, W., Esq., F.R.S.
DAWKINS, Professor W. BOYD, F.R.S.
DE LA RUE, Dr. WARREN, F.R.S.
DEWAR, Professor J., F.R.S.
FLOWER, Professor W. H., F.R.S.
GLADSTONE, Dr. J. H., F.R.S.
GLAISHER, J. W. L., Esq., F.R.S.
GODWIN-AUSTEN, Lieut.-Col. H. H., F.R.S.
HAWKSHAW, J. CLARKE, Esq., F.G.S.
HENRICI, Professor O., F.R.S.
HUGHES, Professor T. MCK., F.G.S.
MARTIN, J. B., Esq., F.S.S.
M'LEOD, Professor H., F.R.S.
MOSELEY, Professor H. N., F.R.S.
OMMANNEY, Admiral Sir E., C.B., F.R.S.
PENGELLY, W., Esq., F.R.S.
PERKIN, Dr. W. H., F.R.S.
SORBY, Dr. H. C., F.R.S.
TEMPLE, Sir R., Bart., G.C.S.I.
THISELTON-DYER, W. T., Esq., C.M.G., F.R.S.

GENERAL SECRETARIES.

Capt. DOUGLAS GALTON, C.B., D.C.L., LL.D., F.R.S., F.G.S., 12 Chester Street, London, S.W.
A. G. VERNON HARCOURT, Esq., M.A., LL.D., F.R.S., F.C.S., Cowley Grange, Oxford.

SECRETARY.

ARTHUR T. ATCHISON, Esq., M.A., 22 Albemarle Street, London, W.

GENERAL TREASURER.

Professor A. W. WILLIAMSON, Ph.D., LL.D., F.R.S., F.C.S., University College, London, W.C.

EX-OFFICIO MEMBERS OF THE COUNCIL.

The Trustees, the President and President Elect, the Presidents of former years, the Vice-Presidents and Vice-Presidents Elect, the General and Assistant General Secretaries for the present and former years, the Secretary, the General Treasurers for the present and former years, and the Local Treasurer and Secretaries for the ensuing Meeting.

TRUSTEES (PERMANENT).

Sir JOHN LUBBOCK, Bart., M.P., D.C.L., LL.D., F.R.S., Pres. L.S.
The Right Hon. Lord RAYLEIGH, M.A., D.C.L., LL.D., Sec.R.S., F.R.A.S.
The Right Hon. Sir LYON PLAYFAIR, K.C.B., M.P., Ph.D., LL.D., F.R.S.

PRESIDENTS OF FORMER YEARS.

The Duke of Devonshire, K.G.
Sir G. B. Airy, K.C.B., F.R.S.
The Duke of Argyll, K.G., K.T.
Sir Richard Owen, K.C.B., F.R.S.
Sir W. G. Armstrong, C.B., LL.D.
Sir William R. Grove, F.R.S.
Sir Joseph D. Hooker, K.C.S.I.
Prof. Stokes, D.C.L., Pres. R.S.
Prof. Huxley, LL.D., F.R.S.
Prof. Sir Wm. Thomson, LL.D.
Prof. Williamson, Ph.D., F.R.S.
Prof. Tyndall, D.C.L., F.R.S.
Sir John Hawkshaw, F.R.S.
Prof. Allman, M.D., F.R.S.
Sir A. C. Ramsay, LL.D., F.R.S.
Sir John Lubbock, Bart., F.R.S.
Prof. Cayley, LL.D., F.R.S.
Lord Rayleigh, D.C.L., Sec.R.S.

GENERAL OFFICERS OF FORMER YEARS.

F. Galton, Esq., F.R.S.
Dr. T. A. Hirst, F.R.S.
Dr. Michael Foster, Sec. R.S.
George Griffith, Esq., M.A., F.C.S.
P. L. Sclater, Esq., Ph.D., F.R.S.
Prof. Bonney, D.Sc., F.R.S.

AUDITORS.

John Evans, Esq., D.C.L., F.R.S. | W. Huggins, Esq., D.C.L., F.R.S. | W. H. Preece, Esq., F.R.S.

LIST OF MEMBERS

OF THE

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

1885.

* indicates Life Members entitled to the Annual Report.
§ indicates Annual Subscribers entitled to the Annual Report.
‡ indicates Subscribers not entitled to the Annual Report.
Names without any mark before them are Life Members not entitled to the Annual Report.
Names of Members of the GENERAL COMMITTEE are printed in SMALL CAPITALS.
Names of Members whose addresses are incomplete or not known are in *italics*.

Notice of changes of residence should be sent to the Secretary, 22 Albemarle Street, London, W.

Year of Election.

Abbatt, Richard, F.R.A.S. Marlborough House, Burgess Hill, Sussex.
1881. *Abbott, R. T. G. Woodbine House, Trinity-road, Scarborough.
1863. *ABEL, Sir FREDERICK AUGUSTUS, C.B., D.C.L., F.R.S., F.C.S., Director of the Chemical Establishment of the War Department. Royal Arsenal, Woolwich.
1856. ‡Abercrombie, John, M.D. 39 Welbeck-street, London, W.
1885. *ABERDEEN, The Right Hon. the Earl of, LL.D. 37 Grosvenor-square, London, W.
1885. §Aberdeen, The Countess of. 37 Grosvenor-square, London, W.
1885. §Abernethy, David W. Ferryhill Cottage, Aberdeen.
1863. *ABERNETHY, JAMES, M.Inst.C.E., F.R.S.E. 4 Delahay-street, Westminster, S.W.
1885. §Abernethy, James W. 2 Rubislaw-place, Aberdeen.
1873. *ABNEY, Captain W. DE W., R.E., F.R.S., F.R.A.S., F.C.S. Willeslie House, Wetherby-road, South Kensington, London, S.W.
1877. §Ace, Rev. Daniel, D.D., F.R.A.S. Laughton, near Gainsborough, Lincolnshire.
1884. ‡Achison, George. Collegiate Institute, Toronto, Canada.
1873. ‡Ackroyd, Samuel. Greaves-street, Little Horton, Bradford, Yorkshire.

Year of Election.

1882. *Acland, Alfred Dyke. Oxford.
1869. ‡Acland, Charles T. D., M.P. Sprydoncote, Exeter.
1877. *Acland, Francis E. Dyke, R.A. School of Gunnery, Shoeburyness.
1873. *Acland, Rev. H. D., M.A. Nymet St. George, South Molton, Devon.
1873. *ACLAND, Sir HENRY W. D., K.C.B., M.A., M.D., LL.D., F.R.S., F.R.G.S., Radcliffe Librarian and Regius Professor of Medicine in the University of Oxford. Broad-street, Oxford.
1877. *Acland, Theodore Dyke, M.A. 79 Lambeth Palace-road, London, S.E.
1860. ‡ACLAND, Sir THOMAS DYKE, Bart., M.A., D.C.L., M.P. Sprydoncote, Exeter; and Athenæum Club, London, S.W.
1884. ‡Adams, Frank Donovan. Geological Survey, Ottawa, Canada.
1876. ‡Adams, James. 9 Royal-crescent West, Glasgow.
*ADAMS, JOHN COUCH, M.A., LL.D., F.R.S., F.R.A.S., Director of the Observatory and Lowndean Professor of Astronomy and Geometry in the University of Cambridge. The Observatory, Cambridge.
1871. §Adams, John R. 3 Queen's-gate-terrace, London, S.W.
1879. *ADAMS, Rev. THOMAS, M.A. Underhill, Low Fell, Gateshead.
1877. ‡ADAMS, WILLIAM. 3 Sussex-terrace, Plymouth.
1869. *ADAMS, WILLIAM GRYLLS, M.A., F.R.S., F.G.S., F.C.P.S., Professor of Natural Philosophy and Astronomy in King's College, London. 43 Notting Hill-square, London, W.
1873. ‡Adams-Acton, John. Margutta House, 103 Marylebone-road, London, N.W.
1879. ‡Adamson, Robert, M.A., LL.D., Professor of Logic and Political Economy in Owens College, Manchester. 60 Parsonage-road, Withington, Manchester.
1860. *Adie, Patrick. Broadway, Westminster, S.W.
1865. *Adkins, Henry. Northfield, near Birmingham.
1883. §Adshead, Samuel. School of Science, Macclesfield.
1884. ‡Agnew, Cornelius R. 266 Maddison-avenue, New York, U.S.A.
1884. ‡Aikins, Dr. W. T. Jarvis-street, Toronto, Canada.
1864. *Ainsworth, David. The Flosh, Cleator, Carnforth.
1871. *Ainsworth, John Stirling. Harecroft, Cumberland.
Ainsworth, Peter. Smithills Hall, Bolton.
1871. ‡Ainsworth, William M. The Flosh, Cleator, Carnforth.
AIRY, Sir GEORGE BIDDELL, K.C.B., M.A., LL.D., D.C.L., F.R.S., F.R.A.S. The White House, Croom's Hill, Greenwich, S.E.
1871. §Aitken, John, F.R.S.E. Darroch, Falkirk, N.B.
Akroyd, Edward. Bankfield, Halifax.
1884. *Alabaster, H. 22 Paternoster-row, London, E.C.
1862. ‡ALCOCK, Sir RUTHERFORD, K.C.B., D.C.L., F.R.G.S. The Athenæum Club, Pall Mall, London, S.W.
1861. *Alcock, Thomas, M.D. Oakfield, Sale, Manchester.
*Aldam, William. Frickley Hall, near Doncaster.
1883. ‡Alexander, George. Kildare-street Club, Dublin.
1873. ‡Alexander, Reginald, M.D. 13 Hallfield-road, Bradford, Yorkshire.
1858. ‡ALEXANDER, WILLIAM, M.D. Halifax.
1850. ‡Alexander, Rev. William Lindsay, D.D., F.R.S.E. Pinkieburn, Musselburgh, by Edinburgh.
1883. §Alger, Miss Ethel. Widey Court, near Plymouth.
1883. §Alger, W. H. Widey Court, near Plymouth.
1883. §Alger, Mrs. W. H. Widey Court, near Plymouth.
1867. ‡Alison, George L. C. Dundee.
1859. ‡Allan, Alexander. Scottish Central Railway, Perth.
1885. §Allan, David. West Cults, near Aberdeen.

Year of Election.

1871. ‡Allan, G., M.Inst.C.E. 101 Leadenhall-street, London, E.C.
1871. ‡ALLEN, ALFRED H., F.C.S. 1 Surrey-street, Sheffield.
1879. *Allen, Rev. A. J. C. The College, Chester.
1884. §Allen, Rev. George. Shaw Vicarage, Oldham.
1878. ‡Allen, John Romilly. 5 Albert-terrace, Regent's Park, London, N.W.
1861. ‡Allen, Richard. Didsbury, near Manchester.
1863. ‡Allhusen, C. Elswick Hall, Newcastle-on-Tyne.
*ALLMAN, GEORGE J., M.D., LL.D., F.R.S. L. & E., M.R.I.A., F.L.S., Emeritus Professor of Natural History in the University of Edinburgh. Ardmore, Parkstone, Dorset.
1873. ‡Ambler, John. North Park-road, Bradford, Yorkshire.
1883. §Amery, John Sparke. Druid House, Ashburton, Devon.
1883. §Amery, Peter Fabyan Sparke. Druid House, Ashburton, Devon.
1884. ‡Ami, Henry. Geological Survey, Ottawa, Canada.
1876. ‡Anderson, Alexander. 1 St. James's-place, Hillhead, Glasgow.
1878. ‡Anderson, Beresford. Saint Ville, Killiney.

1883. ‡Woods, Dr. G. A., F.R.S.E., F.R.M.S. Carlton House, 57 Hoghton-street, Southport.
WOODS, SAMUEL. 1 Drapers'-gardens, Throgmorton-street, London, E.C.
*WOODWARD, C. J., B.Sc. 97 Harborne-road, Birmingham.
1866. ‡WOODWARD, HENRY, LL.D., F.R.S., F.G.S., Keeper of the Department of Geology, British Museum (Natural History), Cromwell-road, London, S.W.
1870. ‡WOODWARD, HORACE B., F.G.S. Geological Museum, Jermyn-street, London, S.W.
1881. §Wooler, W. A. Sadberge Hall, Darlington.

Year of Election.

1884. *Woolcock, Henry. Rickerby House, St. Bees.
1877. ‡Woollcombe, Robert W. 14 Acre-place, Stoke, Devonport.
1883. *Woolley, George Stephen. 69 Market-street, Manchester.
1856. ‡Woolley, Thomas Smith, jun. South Collingham, Newark.
WORCESTER, The Right Rev. HENRY PHILPOTT, D.D., Lord Bishop of. Hartlebury Castle, Kidderminster.
1874. ‡Workman, Charles. Ceara, Windsor, Belfast.
1878. ‡Wormell, Richard, M.A., D.Sc. Roydon, near Ware, Hertfordshire.
1863. *Worsley, Philip J. Rodney Lodge, Clifton, Bristol.
1855. *Worthington, Rev. Alfred William, B.A. Stourbridge, Worcestershire.
Worthington, Archibald. Whitchurch, Salop.
Worthington, James. Sale Hall, Ashton-on-Mersey.
1856. ‡Worthy, George S. 2 Arlington-terrace, Mornington-crescent, Hampstead-road, London, N.W.
1884. ‡Wragge, Edmund. 109 Wellesley-street, Toronto, Canada.
1879. §Wrentmore, Francis, 34 Holland Villas-road, Kensington, London, S.W.
1883. *Wright, Rev. Arthur, M.A. Queen's College, Cambridge.
1883. *Wright, Rev. Benjamin, M.A. The Rectory, Darlaston.
1871. §WRIGHT, C. R. A., D.Sc., F.R.S., F.C.S., Lecturer on Chemistry in St. Mary's Hospital Medical School, Paddington, London, W.
1861. *Wright, E. Abbot. Castle Park, Frodsham, Cheshire.
1857. ‡WRIGHT, E. PERCEVAL, M.A., M.D., F.L.S., M.R.I.A., Professor of Botany, and Director of the Museum, Dublin University. 5 Trinity College, Dublin.
1884. ‡Wright, Harrison. Wilkes' Barré, Pennsylvania, U.S.A.
1876. ‡Wright, James. 114 John-street, Glasgow.
1874. ‡Wright, Joseph. Cliftonville, Belfast.
1865. ‡Wright, J. S. 168 Brearley-street West, Birmingham.
1884. ‡Wright, Professor R. Ramsay, M.A., B.Sc. University College, Toronto, Canada.
WRIGHT, T. G., M.D. Milnes House, Wakefield.
1876. ‡Wright, William. 31 Queen Mary-avenue, Glasgow.
1871. ‡Wrightson, Thomas, M.Inst.C.E., F.G.S. Norton Hall, Stockton-on-Tees.
1867. ‡*Wünsch, Edward Alfred. 146 West George-street, Glasgow.*
Wyld, James, F.R.G.S. Charing Cross, London, W.C.
1867. ‡Wylie, Andrew. Prinlaws, Fifeshire.
1884. ‡Wylie, Professor Theophilus A. Bloomington, Indiana, U.S.A.
1883. ‡Wyllie, Andrew. 10 Park-road, Southport.
1885. §Wyness, James D., M.D. 53 School-hill, Aberdeen.
1871. ‡Wynn, Mrs. Williams. Cefn, St. Asaph.
1862. ‡WYNNE, ARTHUR BEEVOR, F.G.S. Geological Survey Office, 14 Hume-street, Dublin.

1875. ‡Yabbicom, Thomas Henry, C.E. 37 White Ladies-road, Clifton, Bristol.
*Yarborough, George Cook. Camp's Mount, Doncaster.
1865. ‡Yates, Edwin. Stonebury, Edgbaston, Birmingham.
Yates, James. Carr House, Rotherham, Yorkshire.
1883. ‡Yates, James. Public Library, Leeds.
1867. ‡Yeaman, James. Dundee.
1884. ‡Yee, Fung, Secretary to the Chinese Legation. 49 Portland-place, London, W.
1879. ‡Yeomans, John. Upperthorpe, Sheffield.

Year of Election.

1877. ‡Yonge, Rev. Duke. Puslinch, Yealmpton, Devon.

1879. *York, His Grace the Archbishop of, D.D., F.R.S. The Palace, Bishopthorpe, Yorkshire.

1884. §York, Frederick. 87 Lancaster-road, Notting Hill, London, W.

1884. ‡Young, Frederick. 5 Queensberry-place, London, S.W.

1884. ‡Young, Professor George Paxton. 121 Bloor-street, Toronto, Canada.

1876. *Young, James, F.C.S. Kelly, Wemyss Bay, by Greenock.

1876. ‡Young, John, M.D., Professor of Natural History in the University of Glasgow. 38 Cecil-street, Hillhead, Glasgow.

1885. §Young, R. Bruce. 8 Crown-gardens, Dowanhill, Glasgow.

1883. *Young, Sydney, D.Sc. University College, Bristol.

1868. ‡Youngs, John. Richmond Hill, Norwich.

1876. ‡Yuille, Andrew. 7 Sardinia-terrace, Hillhead, Glasgow.

1871. ‡Yule, Colonel Henry, C.B., F.R.G.S. 3 Penywern-road, South Kensington, London, S.W.

CORRESPONDING MEMBERS.

Year of Election.

1871. HIS IMPERIAL MAJESTY THE EMPEROR OF THE BRAZILS.
1881. Professor G. F. Barker. University of Pennsylvania, Philadelphia.
1870. Professor Van Beneden, LL.D. Louvain, Belgium.
1880. Professor Ludwig Boltzmann. Halbärtgasse, 1, Gräz, Austria.
1884. Professor H. P. Bowditch, M.D. Boston, Massachusetts, United States.
1884. Professor George J. Brush. Yale College, New Haven, United States.
1864. Dr. H. D. Buys-Ballot, Superintendent of the Royal Meteorological Institute of the Netherlands. Utrecht, Holland.
1861. Dr. Carus. Leipzig.
1882. Dr. R. Clausius, Professor of Physics. The University, Bonn.
1855. Dr. Ferdinand Cohn. Breslau, Prussia.
1871. Professor Dr. Colding. Copenhagen.
1881. Professor Josiah P. Cooke. Harvard University, United States.
1873. Professor Guido Cora. 74 Corso Vittorio Emanuele, Turin.
1880. Professor Cornu. L'École Polytechnique, Paris.
1870. J. M. Crafts, M.D. L'École des Mines, Paris.
1876. Professor Luigi Cremona. The University, Rome.
1872. *Professor M. Croullebois. 18 Rue Sorbonne, Paris.*
1866. Dr. Geheimrath von Dechen. Bonn.
1862. Wilhelm Delffs, Professor of Chemistry in the University of Heidelberg.
1864. M. Des Cloizeaux. Paris.
1872. Professor G. Dewalque. Liége, Belgium.
1870. Dr. Anton Dohrn. Naples.
1882. Dr. Emil Du Bois-Reymond, Professor of Physiology. The University, Berlin.
1881. Captain J. B. Eads, M.Inst.C.E. St. Louis, United States.
1876. Professor Alberto Eccher. Florence.
1861. Professor A. Favre. Geneva.
1874. Dr. W. Feddersen. Leipzig.
1872. W. de Fonvielle. 50 Rue des Abbesses, Paris.
1856. Professor E. Frémy. L'Institut, Paris.
1842. *M. Frisiani.*
1881. C. M. Gariel, Secretary of the French Association for the Advancement of Science. 4 Rue Antoine Dubois, Paris.
1866. Dr. Gaudry. Paris.
1861. Dr. Geinitz, Professor of Mineralogy and Geology. Dresden.
1884. Professor J. Willard Gibbs. Yale College, New Haven, United States.
1884. Professor Wolcott Gibbs. Harvard University, United States.
1870. Governor Gilpin. Colorado, United States.

Year of Election.

1876. Dr. Benjamin A. Gould, Director of the Argentine National Observatory, Cordoba.
1852. Professor Asa Gray, LL.D. Harvard University, United States.
1884. Major A. W. Greely. Washington, United States.
1871. *Dr. Paul Güssfeld. 33 Meckenheimer-strasse, Bonn, Prussia.*
1862. Dr. D. Bierens de Haan, Member of the Royal Academy of Sciences, Amsterdam. Leiden, Holland.
1876. Professor Ernst Haeckel. Jena.
1881. Dr. Edwin H. Hall. Baltimore, United States.
1872. Professor James Hall. Albany, State of New York.
1881. M. Halphen. 21 Rue Ste. Anne, Paris.
1864. M. Hébert, Professor of Geology in the Sorbonne, Paris.
1877. Professor H. L. F. von Helmholtz. Berlin.
1872. J. E. Hilgard, Assist.-Supt. U.S. Coast Survey. Washington, United States.
1881. Dr. A. A. W. Hubrecht. Leiden.
1876. Professor von Quintus Icilius. Hanover.
1884. Professor C. Loring Jackson. Harvard University, Cambridge, Massachusetts, United States.
1867. *Dr. Janssen, LL.D. 21 Rue Labat* (18° *Arrondissement*), *Paris.*
1876. Dr. W. J. Janssen. Davos-Doerfli, Graubunden, Switzerland.
1862. Charles Jessen, Med. et Phil. Dr. Kastanienallee, 69, Berlin.
1881. W. Woolsey Johnson, Professor of Mathematics in the United States Naval Academy. Annapolis, United States.
1876. Dr. Giuseppe Jung. 9 Via Monte Pietà, Milan.
1877. *M. Akin Kàroly. 5 Babenberger-strasse, Vienna.*
1862. Aug. Kekulé, Professor of Chemistry. Bonn.
1884. Professor Dairoku Kikuchi. Tokio, Japan.
1873. Dr. Felix Klein. The University, Leipzig.
1874. Dr. Knoblauch. Halle, Germany.
1856. Professor A. Kölliker. Wurzburg, Bavaria.
1856. Laurent-Guillaume De Koninck, M.D., Professor of Chemistry and Palæontology in the University of Liége, Belgium.
1877. Dr. Hugo Kronecker, Professor of Physiology. 35 Dorotheen-strasse, Berlin.
1882. Professor S. P. Langley. Allegheny, United States.
1876. Professor von Lasaulx. Breslau.
1872. M. Georges Lemoine. 76 Rue d'Assas, Paris.
1883. Dr. F. Lindemann, Professor of Mathematics in the University of Königsberg.
1877. Dr. M. Lindemann, Hon. Sec. of the Bremen Geographical Society, Bremen.
1871. Professor Jacob Lüroth. The University, Freiburg, Germany.
1871. Dr. Lütken. Copenhagen.
1869. Professor C. S. Lyman. Yale College, New Haven, United States.
1867. Professor Mannheim. Rue de la Pompe, 11, Passy, Paris.
1881. Professor O. C. Marsh. Yale College, New Haven, United States.
1867. Professor Ch. Martins, Director of the Jardin des Plantes. Montpellier, France.
1884. Albert A. Michelson. Cleveland, Ohio, United States.
1848. Professor J. Milne-Edwards. Paris.
1855. *M. l'Abbé Moigno. Paris.*
1877. Professor V. L. Moissenet. L'École des Mines, Paris.
1864. Dr. Arnold Moritz. The University, Dorpat, Russia.
1866. Chevalier C. Negri, President of the Italian Geographical Society, Turin, Italy.
1864. Herr Neumayer. Deutsche Seewarte, Hamburg.

Year of Election.

1884. Professor Simon Newcomb. Washington, United States.
1869. Professor H. A. Newton. Yale College, New Haven, United States.
1874. M. A. Niaudet. 6 Rue du Seine, Paris.
1856. M. E. Peligot, Memb. de l'Institut, Paris.
1857. Gustave Plarr, D.Sc. 22 Hadlow-road, Tunbridge, Kent.
1870. Professor Felix Plateau. 64 Boulevard du Jardin Zoologique, Gand, Belgium.
1884. Major J. W. Powell, Director of the Geological Survey of the United States. Washington, United States.
1886. Professor Putnam, Secretary of the American Association for the Advancement of Science. Washington, United States.
1868. L. Radlkofer, Professor of Botany in the University of Munich.
1882. Professor G. vom Rath. Bonn.
1884. Captain P. H. Ray. Washington, United States.
1886. Rev. A. Renard. Royal Museum, Brussels.
1872. Professor Victor von Richter. St. Petersburg.
1873. Baron von Richthofen. The University, Leipzig.
M. de la Rive. Geneva.
1866. F. Römer, Ph.D., Professor of Geology and Palæontology in the University of Breslau. Breslau, Prussia.
1881. Professor Henry A. Rowland. Baltimore, United States.
1857. Professor Robert Schlagintweit. Giessen.
1857. Baron Herman de Schlagintweit-Sakünlünski. Jaegersberg Castle, near Forchheim, Bavaria.
1883. Dr. Ernst Schröder. Karlsruhe, Baden.
1886. Dr. Max Schuster. The University, Vienna.
1874. Dr. G. Schweinfurth. Cairo.
1846. Baron de Selys-Longchamps. Liége, Belgium.
1872. Professor Carl Semper. Wurzburg, Bavaria.
1873. Dr. A. Shafarik. Prague.
1861. Dr. Werner Siemens. Berlin.
1849. Dr. Siljeström. Stockholm.
1876. Professor R. D. Silva. L'École Centrale, Paris.
1864. Adolph Steen, Professor of Mathematics. Copenhagen.
1866. Professor Steenstrup. Copenhagen.
1881. Dr. Cyparissos Stephanos. 28 Rue de l'Arbaléte, Paris.
1881. Professor Sturm. Münster, Westphalia.
1871. Dr. Joseph Szabó. Pesth, Hungary.
1870. Professor Tchebichef, Membre de l'Académie de St. Pétersbourg.
1852. M. Pierre de Tchihatchef, Corresponding Member of the Institute of France. 1 Piazza degli Zuaai, Florence.
1884. Professor Robert H. Thurston. Stevens Institute of Technology, Hoboken, New Jersey, United States.
1864. Dr. Otto Torell, Professor of Geology in the University of Lund, Sweden.
Arminius Vámbéry, Professor of Oriental Languages in the University of Pesth, Hungary.
1886. M. Jules Vuylsteke. 80 Rue de Lille, Menin, Belgium.
1842. Professor Wartmann. Geneva.
1881. Professor H. M. Whitney. Beloit College, Wisconsin, United States.
1874. Professor Wiedemann. Leipzig.
1876. Professor Adolph Wüllner. Aix-la-Chapelle.
1875. Dr. E. L. Youmans. New York, United States.

GENERAL LIST OF WORKS.

ALBERT MEMORIAL. A Descriptive and Illustrated Account of the National Monument at Kensington. Illustrated by numerous Engravings. With Descriptive Text. By DOYNE C. BELL. With 24 Plates. Folio. 12*l*. 12*s*.

———— HANDBOOK TO. Post 8vo. 1*s*.; or Illustrated Edition, 2*s*. 6*d*.

————(PRINCE) SPEECHES AND ADDRESSES. Fcap. 8vo. 1*s*.

ABBOTT (REV. J.). Memoirs of a Church of England Missionary in the North American Colonies. Post 8vo. 2*s*.

ABERCROMBIE (JOHN). Enquiries concerning the Intellectual Powers and the Investigation of Truth. Fcap. 8vo. 3*s*. 6*d*.

ACLAND (REV. C.). The Manners and Customs of India. Post 8vo. 2*s*.

ADMIRALTY PUBLICATIONS; Issued by direction of the Lords Commissioners of the Admiralty:—

CHALLENGER EXPEDITION, 1873—1876: Report of the Scientific Results of. ZOOLOGY. Vol. I. 37*s*. 6*d*. Vol. II. 50*s*. Vol. III. 50*s*. Vol. IV. 50*s*. Vol. V. 50*s*. Vol. VI. 42*s*. Vol. VII. 30*s*. Vol. VIII. 40*s*.

A MANUAL OF SCIENTIFIC ENQUIRY, for the Use of Travellers. Edited by R. MAIN, M.A. Woodcuts. Post 8vo. 3*s*. 6*d*.

GREENWICH ASTRONOMICAL OBSERVATIONS, 1837 to 1880. Royal 4to. 20*s*. each.

GREENWICH ASTRONOMICAL RESULTS, 1847 to 1881. 4to. 3*s*. each.

MAGNETICAL AND METEOROLOGICAL OBSERVATIONS, 1841 to 1847. Royal 4to. 20*s*. each.

MAGNETICAL AND METEOROLOGICAL RESULTS, 1848 to 1881. 4to. 3*s*. each.

APPENDICES TO OBSERVATIONS.

1837. Logarithms of Sines and Cosines in Time. 3*s*.
1842. Catalogue of 1439 Stars, from Observations made in 1836, 1841. 4*s*.
1845. Longitude of Valentia (Chronometrical) 3*s*.
1847. I. Description of Altazimuth. 3*s*.
III. Description of Photographic Apparatus. 2*s*.
1851. Maskelyne's Ledger of Stars. 3*s*.
1852. I. Description of the Transit Circle. 3*s*.
1853. Bessel's Refraction Tables. 3*s*
1854. I. Description of the Reflex Zenith Tube. 3*s*.
II. Six Years' Catalogue of Stars from Observations. 1848 to 1853. 4*s*.
1860. Reduction of Deep Thermometer Observations. 2*s*.
1862. II. Plan of Ground and Buildings of Royal Observatory, Greenwich. 3*s*.
III. Longitude of Valentia (Galvanic). 2*s*.
1864. I. Moon's Semi-diameter, from Occultations. 2*s*.
II. Reductions of Planetary Observations. 1831 to 1835. 2*s*.
1868. I. Corrections of Elements of Jupiter and Saturn. 2*s*.
II. Second Seven Years' Catalogue of 2760 Stars. 1861-7. 4*s*.
III. Description of the Great Equatorial. 3*s*.
1871. Description of Water Telescope. 3*s*.
1873. Regulations of the Royal Observatory. 2*s*.
1876. II. Nine Years' Catalogue of 2283 Stars. 1868-76. 6*s*.
1879. Description of Greenwich Time Signal System. 2*s*.

B

ADMIRALTY PUBLICATIONS—*continued.*

Cape of Good Hope Observations (Star Ledgers). 1856 to 1863. 2s.
———— 1856. 5s.
———— Astronomical Results. 1857 to 1858. 5s.
Cape Catalogue, 1834 to 1840, reduced to Epoch 1840. 7s. 6d.
———— of 1159 Stars, 1856 to 1881, reduced to the Epoch 1860. 3s.
————, 12,441 Stars for Epoch 1880. 31s. 6d.
Cape of Good Hope Astronomical Results. 1859 to 1860. 5s.
———— 1871 to 1873. 5s.
———— 1874 to 1876. 5s. each.
Report on Teneriffe Astronomical Experiment. 1856. 5s.
Observations on the Transit of Venus, 1874. 20s.
Paramatta Catalogue of 7385 Stars. 1822 to 1826. 4s.

REDUCTION OF THE OBSERVATIONS OF PLANETS. 1750 to 1830. Royal 4to. 20s. each.

———— LUNAR OBSERVATIONS. 1750 to 1830. 2 Vols. Royal 4to. 20s. each.

———— 1831 to 1851. 4to. 10s. each.

ARCTIC PAPERS. 13s. 6d.

BERNOULLI'S SEXCENTENARY TABLE. 1779. 4to. 5s.

BESSEL'S AUXILIARY TABLES FOR HIS METHOD OF CLEARING LUNAR DISTANCES. 8vo. 2s.

ENCKE'S BERLINER JAHRBUCH, for 1830. *Berlin*, 1828. 8vo.

HANNYNGTON'S HAVERSINES. 21s.

HANSEN'S TABLES DE LA LUNE. 4to. 20s.

LAX'S TABLES FOR FINDING THE LATITUDE AND LONGITUDE. 1821. 8vo. 10s.

LUNAR OBSERVATIONS at GREENWICH. 1783 to 1819. Compared with the Tables, 1821. 4to. 7s. 6d.

MACLEAR ON LACAILLE'S ARC OF MERIDIAN. 2 Vols. 20s. each.

MAYER'S DISTANCES of the MOON'S CENTRE from the PLANETS. 1822, 3s.; 1823, 4s. 6d. 1824 to 1835. 8vo. 4s. each.

MAYER'S TABULÆ MOTUUM SOLIS ET LUNÆ. 1770. 5s.

———— ASTRONOMICAL OBSERVATIONS MADE AT GÖTTINGEN, from 1756 to 1761. 1826. Folio. 7s. 6d.

NAUTICAL ALMANACS, from 1767 to 1887. 2s. 6d. each.

———— SELECTIONS FROM, up to 1812. 8vo. 5s. 1834-54. 5s.

———— SUPPLEMENTS, 1828 to 1833, 1837 and 1838. 2s. each.

———— TABLE requisite to be used with the N.A. 1781. 8vo. 5s.

SABINE'S PENDULUM EXPERIMENTS to DETERMINE THE FIGURE OF THE EARTH. 1825. 4to. 40s.

SHEPHERD'S TABLES for CORRECTING LUNAR DISTANCES. 1772. Royal 4to. 21s.

———— TABLES, GENERAL, of the MOON'S DISTANCE from the SUN, and 10 STARS. 1787. Folio. 5s. 6d.

TAYLOR'S SEXAGESIMAL TABLE. 1780. 4to. 15s.

———— TABLES OF LOGARITHMS. 4to. 60s.

TIARK'S ASTRONOMICAL OBSERVATIONS for the LONGITUDE of MADEIRA. 1822. 4to. 5s.

———— CHRONOMETRICAL OBSERVATIONS for DIFFERENCES of LONGITUDE between DOVER, PORTSMOUTH, and FALMOUTH. 18[illegible]. 4to. 5s.

VENUS and JUPITER: OBSERVATIONS of, compared with the TABLES. *London*, 1822. 4to. 2s.

WALES AND BAYLY'S ASTRONOMICAL OBSERVATIONS. 1777. 4to. 21s.

———— REDUCTION OF ASTRONOMICAL OBSERVATIONS MADE IN THE SOUTHERN HEMISPHERE. 1764—1771. 1788. 4to. 10s. 6d.

ÆSOP'S FABLES. A New Version. By REV. THOMAS JAMES. With 100 Woodcuts, by TENNIEL and WOLFE. Post 8vo. 2s. 6d.

AGRICULTURAL (ROYAL) JOURNAL. (*Published half-yearly.*)

ALICE; GRAND DUCHESS OF HESSE. Letters to H.M. THE QUEEN. A New and Popular Edition With a Memoir by H.R.H. Princess Christian. Portrait. Crown 8vo. 7*s.* 6*d.*, or Original Edition, 12*s.*
